This is a practice that can, with advantage, be adapted by all who auscultate the chest.

Any simple procedure that facilitates and makes easier the physical diagnosis of everyday medicine is worthy of adoption.

The question must arise as to the likelihood of the two diastolic murmurs, heard so nearly together on the chest wall, being caused by the same or different etiologic factors.

Here there is a great advantage in being familiar with the natural history and progress of rheumatic endocarditis.

It is unusual for rheumatic disease to attack other than the mitral valve in the first attack of acute rheumatic fever.

Aortic valvulitis is, as a rule, a complication or sequel of the second or of still later attacks of this devastating disease.

We can be almost certain that the mitral valve was involved long before the aortic valve and that we are now dealing, in this particular patient, with extensive pathologic changes in both the mitral and aortic valves.

Fortunately it is relatively rare in rheumatic hearts to have the pulmonary and tricuspid valves involved with structural lesions.

Another helpful aid in deciding whether the two diastolic

murmurs have the same valvular cause is that the two murmurs are absolutely unlike in quality of sound.

The murmur heard over the body of the heart is a prolonged soft adventitious sound while the murmur heard above the apex is harsh and has a crescendo quality which merges with the systolic murmur that replaces the first sound at the apex of the heart.

One is justified in diagnosing, in the presence of the physical signs recited in this patient, the existence of chronic endocarditis of both the mitral and aortic valves.

We are dealing with both an obstructive and a regurgitant lesion at each valve.

A physician cannot ignore the significance of the history of the patient's father having been afflicted with the same rheumatic heart disorder.

It is becoming more and more evident to observing clinicians that "rheumatism" is, all too frequently, a "family" disease.

Before we allow the patient to dress it is well to call your attention to confirmatory evidence of the presence of an aortic regurgitation by having the blood pressure estimated.

Before we do this it is well to have one of the examiners place his finger upon the radial pulse and then raise the patient's arm above his head. By this procedure one obtains an excellent example of a pulse that has been described as a "pistol-shot" pulse, a receding pulse, the "Corrigan" pulse.

The characteristic pulse is due to the effect of the hypertrophied left ventricle's violent propulsive action in expelling its contents and the subsequent failure of the incompetent aortic valves preventing the return of the column of blood from the aorta into the left ventricle.

The blood pressure readings are 180/0.

If one listens at the elbow before the sphygmomanometer cuff is applied one will hear a loud pulse sound.

It is, therefore, impossible to estimate the diastolic blood pressure by the usual method because of its greatly decreased amount.

In patients in which there exists doubt as to the exact nature of the diastolic murmur heard over the body of the

heart it is, frequently, helpful to ascertain whether the diastolic blood pressure is normal or greatly diminished.

As is true of the majority of patients who have been unfortunate enough to contract severe and, especially, repeated attacks of rheumatism in early life this patient reveals the evidence of the presence of another very common complication of rheumatic heart affections, namely, chronic adhesive pericarditis.

The evidence of this complication is detected by inspection if one examines in a good light the posterior lateral aspects of the left chest. At each ventricular systole the marked retraction of the three lower ribs and intercostal spaces may be both seen and felt.

This physical sign, known as Broadbent's, is worthy of remembrance for if the habit is formed to seek for its presence in all rheumatic disorders of the heart it is surprising how often this characteristic systolic retraction will be found.

The visceral and parietal pericardial surfaces are adherent to each other and the parietal pericardium has grown fast to the diaphragm.

A particularly good reason for considering the presence of the systolic tugging of the left false ribs is that modern surgery, with its effective anesthetics and its delicate and efficient technic, has much to offer certain patients suffering from the effects of specific types of adherent pericardia that were not, formerly, considered amenable to surgery.

You have seen a classical example of the circulatory damage brought about by rheumatic carditis.

You will find that this disease, acute rheumatic fever, is the cause of more cases of endocarditis in patients under forty years of age than any other affection. In the northern Atlantic States this disorder is all too common and many of the worst tragedies of medical practice will be found associated with the disease, its complications and sequels.

The patient whom you have seen has been under our observation for twelve years and during that period he has remained in fair health.

On three occasions during the period named the patient had exhibited signs and symptoms of failing circulation but,

on each occasion, there has been reasonable cause for such seizures.

Each episode that the patient now describes as a "heart attack" was caused by exaggerated psychic or physical stress.

Rest in bed with the administration of opiates has been sufficient to restore the efficiency of the circulation.

Such a patient requires a sympathetic, understanding and interested physician but not necessarily a therapist.

One important psychological factor in treatment is optimism that is, all too frequently, ignored by pessimistic physicians, relatives and friends of the patient.

The attending physician must admit and face the potential dangers that such a condition of the heart causes.

What are these dangers?

They are easy to enumerate but, even under the best of economic conditions, difficult to eliminate.

The ever-present dangers are:

1. Additional attacks of rheumatism.
2. The dangers inherent in acute infections.
3. Failing compensation due to overwork as life progresses.
4. Subacute bacterial endocarditis engrafted upon the already diseased and crippled heart valves.

The physician must have these dangers ever before him, but he must not make the patient's burden of potential invalidism greater by inculcating fear that is, in many instances, a greater menace to happiness than the disease process.

To forcibly impress you with one of the ever-present dangers that such a patient encounters I have, purposely, selected the next patient.

Before having the individual brought before you I wish you to be familiar with his past medical history and to have you particularly note how similar the history is to that of the patient whom you have been studying.

Note the contrast in physical condition although the ages of the patients are, approximately, the same.

The past medical history of the 2 patients is similar to a certain point when the second patient's history becomes tragic as the result of a common complication of his cardiovascular disorder.

We are forced, as a profession, to reluctantly admit that

the sword of Damocles must hang over the health prospects of such patients but we can be happy in the knowledge that many such patients outlive two generations of physicians in spite of the ever-present hazards.

The patient whom I shall now present illustrates, all too graphically, one result of the fall of the Damoclean sword.

**Case II.**—S. J., age thirty-five, American, of Jewish parentage, has been known to our clinic physicians for many years.

At considerable inconvenience S. J. has made himself available as a "demonstration patient" before 16 successive classes of students.

There are numerous physicians established in various communities of our country who are, I am sure, much better diagnosticians than they otherwise could have been as a result of intimate observations and examinations that they were able to, repeatedly, make of the disordered cardiovascular system so cheerfully and patiently exhibited by this helpful patient.

We are indeed sorry that S. J. has, after years of practically symptomless disease, present need of our services.

If we render him as efficient help as he has given us in the past all will be well.

We have the complete medical history, previously taken, which we can read rather than fatigue an already, obviously, sick patient by requesting him to recite that which is an oft-told tale to him.

At ten years of age the man before you had an attack of rheumatic fever. This required, he states, but six weeks to "cure."

When he was twelve years old it was necessary that he spend sixteen weeks in bed with the same disorder and its complications and sequels.

When he, at long last, recovered from this seizure who can blame him for being tired of hospitals, doctors, nurses and the general atmosphere of unwelcome advice and warnings.

S. J. at thirteen years of age, without a mother to guide him, returned to an active life of strenuous athletics.

He played football, basket ball and strenuously sought to become a champion swimmer.

Who can be sure whether this inadvisable activity had

ought to do with the onset of the third attack of rheumatic fever at sixteen years of age?

Many weeks of hospitalization occurred and, shortly after his discharge from the Pennsylvania Hospital, he came under our observation.

It is well to remember that the patient's last attack of rheumatism occurred when he was sixteen years of age. He is now thirty-five years old.

We were early able to persuade him to sacrifice his badly infected tonsils upon the altar of Hygeia.

His subsequent freedom from "sore throats" and arthritic aches and pains made us and the patient feel the wisdom of prophylactic surgery.

For fifteen years the patient has considered himself in fair physical condition but, because of his strenuous work as an expressman, we were never able to, enthusiastically, share the patient's optimistic views.

The patient's wife observed in recent weeks that her husband returned from his work much more fatigued than was his custom and, contrary to his usual habit, he was willing to retire early.

The patient's body surface was hot and he had profuse perspiration during the night but he would not allow his temperature to be estimated.

At last it became evident, even to the patient, that he could not continue his work and he agreed to enter the hospital for an examination and treatment.

It was with difficulty, however, that we were able to persuade the patient to come to us in the ambulance.

We are fortunate to see this sick man on the day that he is to be admitted.

The temperature has been estimated  $101.2^{\circ}$  F., pulse 120, respirations 28.

When we glance at the eyes we see that the surrounding areas are reddened and careful inspection of the inflamed conjunctivae reveals in each small, red, painless areas, a little larger than the head of a pin.

There are painful subcutaneous spots on a finger and on one toe. These came spontaneously and without previous injury.

When we glance at the patient's neck we note the same violent throbbing of the arteries of the neck that we saw in the patient whom we have, so recently, studied.

As we expose the chest for examination those who are near can easily observe that the entire precordia is being made to forcibly pulsate, the apex beat of the heart is markedly displaced to the left and is an interspace lower than normal.

When the examiner's hand is placed over the left lower chest a marked diastolic thrill is felt and when the hand is placed over the base of the heart an even more marked systolic thrill is noted.

The pulsating carotid vessels indicate well the overacting heart action and fingers placed upon these vessels feel a marked systolic thrill.

When we auscultate the heart we find in the mitral area a to and fro murmur of marked intensity and auscultation over the base of the heart reveals an even louder double murmur.

Over the body of the heart one hears, in addition to the murmurs, a marked pericardial friction rub.

This friction rub could easily be mistaken for a double murmur but when the patient is asked to stop breathing for a few seconds one can, easily, distinguish the superficial, so-called "bread-and-butter" friction of the inflamed pericardium.

When we carefully inspect the left chest, posteriorly, we note the same tell-tale and revealing retraction of the lower interspaces that we observed in the previous patient.

The retraction is caused by a long-standing adherent pericardium firmly attached to the diaphragm.

This is a particularly interesting finding when we stop to consider that over the body of the pericardium there can, at this time, be heard evidence of a fresh pericarditis.

These findings indicate what we know to be the truth, namely, that certain areas of the pericardium may be involved in former inflammation while other areas escape.

When we expose the upper abdomen for inspection a violent pulsation of the epigastrium can be seen and we note, too, a slight bulging mass appearing below the left costal margin to the left of the midclavicular line.

This mass in the upper left abdominal quadrant descends

with respiration, is rounded and smooth and is, as you will note by the patient's expression, painful to touch.

An inspection of the right hypochondrium reveals a large and pulsating liver. This, too, is tender to the touch and its lower margin may be found at a level with the umbilicus.

The patient tells us that yesterday, while at his work as an expressman, he lifted a heavy package and felt a sudden and excruciating pain in his upper abdomen, on the left side.

He describes the sensation "as if a bullet hit me."

He was nauseated but was not able to vomit.

It was necessary for him to stop work and he returned to his home by taxicab. The pain in his upper abdomen continued, he slept little during the night and noticed in the morning that each breath exaggerated the pain in his abdomen.

On attempting to touch his abdomen he discovered the lump just beneath his left ribs. The patient states that, for some weeks, he has felt uncomfortable beneath the right costal margin but did not stop work or consult a physician. The patient informs us that, just as he was being lifted into the ambulance, he had a sudden sharp pain in the calf of his left leg.

An examination of this leg reveals no external evidence of a lesion but when one presses the calf muscle there is exaggeration and localization of the pain.

We will now allow the patient to proceed to the ward where suitable measures will be instituted to render him comfortable.

It must be evident to all of you that we have been in the presence of a brave man who has met with a medical catastrophe.

A patient whom we have observed for over fifteen years, the victim of sequels of acute rheumatic fever, practically symptomless, in spite of hard labor has developed one of the dreaded and, unfortunately, fatal complications, namely, sub-acute bacterial endocarditis.

We know that the patient has embolic phenomena in the conjunctivae, in the finger and toe, in the calf muscles and, in addition, has a large painful infarct in his spleen.

Such a combination of ills would cause the most enthusiastic therapist to pause and devoutly wish for more potent remedies.

Medical statisticians inform us that we must expect from

$\frac{1}{2}$  to 2 per cent of the patients with rheumatic endocarditis to develop subacute bacterial endocarditis.

This information illustrates well that this complication is one of the potential dangers that is inherent in the natural history of every patient we see with rheumatic endocarditis.

We must, however, hope that the first patient seen today will have better fortune than the patient we have more recently been examining.

Although this complication must be ever present in a physician's consciousness it is unfair to make the patient carry such a fear in his daily life.

The third patient that I shall bring before you illustrates another extremely common type of cardiovascular disorder.

Just as rheumatic endocarditis represents the most common type of cardiovascular disorder in patients less than forty years of age, hypertensive cardiovascular disease represents the most common variety of circulatory disease encountered in patients who have passed fifty years of age.

It should be remembered, however, that hypertensive cardiovascular disease will be encountered, all too frequently, in patients younger than forty and that rheumatic endocarditis, of long standing but unrecognized, will be, frequently, encountered in elderly patients.

**Case III.**—The patient before you is O. H., age fifty-seven, white, American.

He enters the hospital for the purpose of obtaining a "complete examination."

His chief complaints are two in number:

1. Gradually failing vision.
2. Shortness of breath on exertion.

The patient's past medical history, as given by him, is unusually uneventful. He has no recollection of previous illness and states that he has never consulted a physician.

An occasional "cold" seems the extent of his experience with illness and still it is well to be reminded that memories are not always to be trusted.

In examining this patient a few days since I noted, but did not remind the patient, the presence of two rather extensive abdominal scars.

One is in the region of the appendix and one over the site of the usual inguinal hernia.

It is a common experience to have patients entirely forget hospital experiences of long ago, even when the illness suffered was acute and painful. The taking of a good medical history is a far more difficult procedure than is the performing of a careful physical examination.

Let us see whether it is possible to add to the history as given us by this intelligent and well educated patient.

Do you have headaches?

The answer is affirmative.

When do they occur?

Chiefly when the patient is fatigued, namely, in the afternoon.

Are you dizzy at times? Yes, frequently and, at times, markedly so.

• This is, obviously, from his present statement, one of the trying symptoms that he has to endure.

How long have you noticed the dull, disagreeable sensation in the head that you hesitate to term a headache?

Between one and two years and, of late, these symptoms have been increasing.

Do you students not think that you must be able to ask intelligent questions in a way that will develop what is present but not uppermost in the patient's consciousness?

The average man dreads exaggeration of his symptoms and to avoid this, to him, great evil he is likely to understate all symptoms.

We may now list the symptoms as given:

1. Failing vision.
2. Dull, uncomfortable sensation in head in the afternoon that "some people would probably call headache."
3. Dizziness, especially when arising from the recumbent position or, even when arising from a chair.
4. Shortness of breath, duration two years, much increased of late.

What other symptoms would it be well to ask about?

Are you troubled by any urinary symptoms?

Yes. It has been necessary to rise three or four times during the night.

What of the appetite? "Nothing tastes as it once did."  
No appetite.

What of insomnia? Has slept poorly for several years. Has bad dreams. Thinks he is being smothered and wakes in a cold sweat.

This man informs us confidentially that, although he has had little personal contact with physicians he does not "like" them.

He thinks that they are not quite honest, not quite fair. It is the experience of his friends that has caused this prejudice.

Both the patient and our profession have been unfortunate in his contacts.

Before we have the patient remove his chest clothing I wish to direct your attention to easily distinguished evidences of a real need for the patient to be thoroughly examined.

What does the student associate feel about the appearance of the temporal vessels?

The patient states that his father had similar prominent temporal vessels. His father died of "a stroke" at sixty-one years of age "while in perfect health." Apoplexy "runs in the family."

When we bare the arms it is obvious that the brachial vessels and their branches are both more superficial and more strikingly evident to the eye. When we feel the brachials there is evidence of more thickening and more resistance to pressure than is usual.

The student seated opposite this well built but emaciated man will give us his impression of the size of the heart.

The apex is in the fifth interspace but it is displaced to the left a distance of at least 2 inches from the normal site.

How does the cardiac area feel when the hand is placed over it?

There is a decided increase in the heart impulse and at the apex there seems to be "an impulse so strong as to give the sensation of a systolic thrill."

At the base of the heart is a marked diastolic shock. To determine this one needs only to place a finger on the apex beat or upon the carotid vessel and note that the shock is

not synchronous with the ventricular contraction but occurs immediately after.

This shock is due to the violent closure of the aortic valves when the column of blood in the aorta finds a lack of elasticity in the artery and attempts to return into the ventricle through the competent aortic valves.

When one listens to the mitral area one hears a loud systolic murmur. This murmur is, I feel sure, not due to an endocarditis because there is no history of the etiologic disorder, but is due to the stretching of the mitral valve orifice by the hypertrophy and dilatation of the left ventricle.

Over the aortic area one hears a slight systolic murmur but in diastole there is a sharp, loud and almost metallic snapping sound.

The pressure within the brachial vessels is greatly increased, 280/160.

When we have the patient recumbent I wish you would, particularly, note the violent pulsations of the femoral vessels.

When these vessels are palpated we find them in the same tense condition that is shown by the vessels in the upper extremities. It is entirely unnecessary to cause the patient the expense of visualizing the sclerosis of the arteries by roentgen ray examination.

We should, by constant practice, educate our fingers to the varying feel of normal and abnormal blood vessels.

The patient whom we have examined will come to no harm by admitting him to the medical ward for a bed rest and during his stay he can be thoroughly studied.

The eyegrounds will be, particularly, examined as to the state of the vessels.

Physiotherapeutic measures with restful and relaxing massage will prove, in my judgment, of greater value than drug therapy.

Can we be sure that had we studied this patient fifteen years ago and had he been willing to adopt all of our well meant suggestions for the prophylaxis of vascular pathology that the result would have been so different from what we find today?

There is a well-founded tradition in this man's family that the males die before sixty of vascular accident.

Heredity is, as far as we at present know the most im-

portant single etiologic agency in the disorder known as hypertensive cardiovascular disease.

We know far too little of direct causes, other than lead and other chemical poisons, but it is believed that constitutional deficiencies and the wear and tear of life, especially the emotional stress, have both direct and indirect bearing upon the development and continuance of the extremely common disorder. What are the greatest potential dangers to the patient we have dismissed? Cerebral accidents, hemorrhage or thrombosis, on the one hand and gradually developing failing compensation of the cardiovascular apparatus on the other.

In an age in which man's existence is prolonged to a greater length than at any time in history the medical profession must be prepared for the perfect understanding of the symptoms and signs of an ever-increasing number of chronic degenerative cardiovascular disorders.

Medical students, graduate or undergraduate, cannot be reminded too forcibly that to be of real help to elderly patients one must understand the psychology of oncoming age as well as to be entirely familiar with the physical evidences of senescence.

An intimate familiarity with the mode of thought of aging persons in good health will clarify the problem of the care of the aged sick.

The next and last patient to be shown in today's clinic illustrates another common cardiovascular disorder.

**Case IV.**—J. McN., age forty-seven, white, American of Irish descent.

His chief complaint is that, recently, he has periods, especially at night, when he is unable to "get a good breath."

One glance at the man and you can see that, in his younger years, this man was an athlete.

He has all the appearance and posture of a man who was sure of his body strength.

What has happened to cast doubt in his mind regarding his present state of health?

The history as recited in the dispensary is, to a great extent, negative as far as physical illnesses is concerned.

When he arrived in this country from Ireland he was em-

ployed as a coachman, later as a chauffeur and, more recently, he has been employed as a doorman at one of the fashionable apartment houses of our city.

With premeditation I have accepted the history as given in the dispensary as approximately correct and have asked the patient to appear before you to illustrate a very commonly misinterpreted clinical entity.

The patient's story is suggestive. He was "absolutely well," to use his own expression, until six weeks ago.

At the apartment house where he is employed disturbances are rare but on the night that he developed symptoms of his present malady it was necessary for him to use all his physical strength, plus his reserve energy, to quell a maniacal alcoholic.

This patient succeeded in a difficult and, let us remember, thankless task where a number of men, in cooperation, had failed but during the strenuous struggle with his opponent he felt, as he terms it, "something give way in my chest."

He was weak, nauseated and states that "everything became dark before my eyes."

The patient continued at his work which consisted in opening auto doors and, frequently, using his strength in opening the heavy door of the apartment house.

He had a dull pain over his upper sternum that was relieved in part when he went to bed.

He returned to his work the morning after the episode of physical struggle but since that time has not been in his usual health and good humor. He has consulted several physicians regarding the troublesome pain in his chest who assure him that he has "strained his heart" and that, if he will go slow, all will return to normal.

Three days ago this patient appeared at the dispensary and we were fortunate enough to have him appear before a small section of the class.

There now appears an opportunity to reveal to the larger group the physical signs, emphasize the history, and call attention to the need of imagination in medicine.

Before we delve into the past medical history let us, together, study the physical signs that are so revealing.

The first student calls attention to the fact that there is an

obvious, abnormal pulsation in the neck superior to the junction of the clavicles.

This pulsation of the innominate artery attracts more attention than does the less obvious but distinctly abnormal pulsation of the carotids.

The second student finds that, in spite of the well-muscled and overplump chest of the patient, he can, without difficulty, both see and feel that the apex beat of the heart is displaced far to the left of the normal position and the left border can be easily palpated.

There are no thrills to be palpated but one notices that the patient winces with discomfort if too heavy a hand is used in examining the precordia. Auscultation reveals a systolic murmur at the cardiac apex and another and louder systolic murmur at the aortic cartilage and transmitted into the vessels of the neck.

In this particular patient it is well to point out that no examination of the cardiovascular apparatus can be considered complete unless one has examined the subject in the sitting, recumbent and in the standing, sitting or recumbent position after exercise.

We will ask another student to first confirm the position of the heart before he listens to its sounds and to exclude the possibility of its abnormal position being due to displacement due to pressure from the right pleural cavity.

The student is satisfied that the heart is hypertrophied and suggests that it is also dilated.

The obvious fact that the lips are distinctly cyanosed bears out the latter impression.

The student states that he hears the systolic murmur at the apex and base without difficulty when the patient is in the recumbent position but I notice that he has only auscultated the localized valve areas over the body of the heart and has not, particularly, auscultated over the remaining body of the heart.

When he listens over the left side of the sternum at the fourth costal cartilage he hears a soft murmur which he believes is not synchronous with ventricular systole as ascertained with his finger on the innominate pulsation.

We will ask the next student to confirm the accuracy of

the timing of the murmur. He is agreed that we have the presence of a diastolic murmur over the body of the heart.

You will note that, despite the fact that the patient had two pillows to lie upon, he is relieved to be allowed to sit upright.

To spare the time of the assembled group I ascertained with certainty that the patient's history is free from the usual causes (namely, rheumatism) of valvular endocarditis.

We will have the blood pressure estimated and the student assures me that although the systolic blood pressure varies more than he thinks it should from moment to moment that it approximates 160.

When he attempts to take the diastolic pressure he is disturbed to find that this is even more difficult to be sure of but that the vascular sound in diastole disappears at, approximately, 40 mm. and that, occasionally one can hear the sound as low as 10.

We then have a patient before us that exhibits the classical physical signs of aortitis with aortic regurgitation and resulting hypertrophy and dilatation of the heart.

A frank talk with the patient regarding the possibility of a venereal disease in his younger years is productive of equally frank statements on his part. When he was twenty-two years of age, and while under the influence of alcohol, he exposed himself for the first and only time in his existence to the possibility of venereal disease.

Some four weeks following exposure the patient developed a small, hard sore on his penis that persisted until "a druggist" gave him an ointment to use and, from that time, twenty-five years ago, he has never had a symptom of disease nor, as far as he is aware, has his general strength failed.

We have, gratefully, called upon the laboratory for help and they return word that both the Wassermann and Kahn reactions of the blood are strongly positive.

We are dealing with a luetic aortitis with resulting incompetence of the aortic valve and the history strongly suggests that physical strain brought about the incompetence of the valves that, under ordinary circumstances, might never have appeared.

Luetic cardiovascular diseases exist in every community and the recognition of them depends upon a physician possess-

ing "a high index of suspicion" as to the nature of obscure and unusual cardiovascular manifestations.

No one, other than the physician, has the right to invade the privacy of a patient's ancient and well hidden memories and no one, better than can the doctor, advise against irregular sexual contacts.

The proper understanding and the efficient treatment of this condition must depend upon correct etiologic diagnosis.

Does our duty as physicians stop here? Through the family physician we can, perhaps, aid in throwing light upon a chronic state of invalidism in the patient's wife. There are, perhaps fortunately, no children in this man's home.

His wife, the patient assures me, was the picture of health when she was married but, following several miscarriages, she has, according to the husband's statement, "entered a decline" and is far from well.

**Summary.**—We have studied 4 patients together by the classical method of careful history taking, painstaking physical examination and the laboratory help that one finds available in one's office, namely, blood pressure estimations and urine examinations.

We believe that any well-trained physician who will take the time and devote the thought necessary to make such a systematic survey of his own patients is, in the majority of instances, the safest and best guide for the average patient.

Postgraduate work can be carried out in one's own office and with one's own patients as study material with lasting benefit to both patient and physician.

Each physician has the opportunity for being a more vital influence upon the lives of his patients than any individual with whom they come in contact.

Our opportunities are unexcelled and our responsibilities are, equally, great.

It is helpful to bear in mind that the patient is far more important to understand than is the disease process that affects him or her.

Thorough examinations, carefully kept notes of observations and findings and continued interest in all unexplained symptoms make us worthy of our professional heritage.

May each of us do the day's work as well as we know how. May each keep ever before us the desire to do tomorrow's work more efficiently than today's.

If every physician practiced his art with the thought of the Golden Rule in mind there would be fewer insoluble professional problems.

## CLINIC OF DR. CHARLES C. WOLFERTH

FROM THE ROBINETTE FOUNDATION, MEDICAL CLINIC.  
HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

---

### THE DIAGNOSIS AND TREATMENT OF ACUTE CORONARY OCCLUSION

**Diagnosis.**—Coronary occlusion is sometimes discussed as though it were an independent disease entity. It is really a by-product of some pathologic process involving a coronary artery. Excluding the rare occurrence of embolism, this objectionable by-product results from disease of the artery itself. Various types of arteritis, of which the most important is syphilis, account for a small minority of cases; the vast majority are incident to coronary arteriosclerosis.

There are two major clinical patterns, one corresponding to an acute and the other to a chronic condition. Each pattern is subject to such variation that its recognition is often difficult. Moreover, combinations of the two are constantly encountered. There is one symptom inseparable from both—impairment of cardiac function—which may be so severe as to cause death, or so slight as to go unnoticed by the patient. The acute process is exemplified by the patient who is seized after little or no warning with intolerable constricting substernal pain, requiring large doses of morphine, for relief. He may die suddenly at any moment. If he survives, he is apt to develop, in the course of a day or two, severe heart failure with small, feeble pulse and pulmonary congestion, fever and leukocytosis. In the typical chronic process, heart failure comes on gradually, sometimes over the course of many years. Such phenomena as angina pectoris, paroxysmal nocturnal dyspnea or disturbances in cardiac rhythm may occur. At necropsy both these clinical types may be found to have coronary occlusion in similar locations. If we ask ourselves the reason for the remarkable difference in the behavior, the

only explanation available is that it depends on the rapidity of development of the occluding process and the efficiency of collateral circulation. Most, but not all, of the patients who suffer from an acute stormy attack are found to have had acute thrombosis superimposed on a gradually developing occlusion resulting from arteriosclerosis. This has led to the use of the term "coronary thrombosis" in connection with these attacks. The term is not entirely satisfactory for two reasons: (1) thrombosis, although it may precipitate the acute attack, is but the capstone in the process of occlusion, and (2) thrombosis cannot be found, and presumably has not occurred, in some of the patients who have suffered acute attacks. In the patient with no acute painful attacks except paroxysms of angina pectoris and in whom death results from gradual heart failure, coronary artery thrombosis is not often found at necropsy. Moreover, such a heart rarely shows massive infarction but there is apt to be a mixture of scar and muscle tissue. These differences are foreshadowed by differences in the electrocardiograms in the two types of cases. Although all coronary arteriosclerosis marches relentlessly toward cardiac failure, the cases in which acute episodes are superimposed on the slowly developing arterial process are apt to have a more disastrous course. This is because of the greater damage to heart muscle and the fact that this type of acute damage frequently leads to sudden death (ventricular fibrillation, cardiac rupture or embolism).

A factor that doubtless influences the course of events after coronary occlusion is the condition of neighboring vessels. There is some evidence to indicate that when infarction develops it may depend not only on the size of the artery occluded and the rapidity of occlusion, but also on the patency of the vessels supplying the surrounding area.

One question of considerable interest is the relationship of size of vessel occluded to the production of symptoms. A few years ago, Dr. F. C. Wood and I noted in animal experiments, which included clamping of coronary arteries, that the occlusion of small branches caused injury currents great enough to manifest themselves in the electrocardiograms. It is well known that occlusion of very small vessels without clinical heart disease is common after middle life. The thought has

often been expressed that some minor attacks now labeled angina pectoris, although usually lasting longer than angina and not precipitated by exertion, are really due to occlusion of small arteries. Some of the minor seizures of pain prior to a major attack of coronary occlusion may be of this nature. Sometimes minor and relatively transient electrocardiographic changes are observed in association with such attacks suggesting at least slight acute muscle damage.

The most prominent symptom of acute coronary occlusion is pain. It occurs in nearly every case in which infarction, sufficiently large to be demonstrated by electrocardiogram, is present. Its characteristics have been described so often that it seems unnecessary to repeat them here. A few comments, however, may not be amiss. (1) The pain is not always agonizing or intolerable. The patient may continue at his work thinking he has indigestion or some sort of congestion in his chest. Centering of the pain in the lower substernal or epigastric region, especially when temporary relief is produced by eructation of gas, strengthens his belief that he has indigestion. (2) If a patient subject to attacks of angina pectoris develops a pain of the usual type, which, instead of subsiding promptly, lasts an hour or more, the possibility of coronary occlusion should be considered. Sometimes, however, patients subject to angina pectoris describe the pain during an attack of coronary occlusion as somewhat different in location and quality, as well as intensity and duration. (3) Although the pain is usually centered in the substernal region, with or without radiation, it may be greatest in the precordial region, the upper left breast, shoulders or arms (usually the left but occasionally the right or both), the neck or under the left scapula. There may be a complaint of mid or lower abdominal pain, but if maximum intensity of pain is in these areas, it is due to something other than coronary occlusion. Severe upper right quadrant pain is rarely if ever due to coronary occlusion, although some tenderness and pain may develop in this region following an attack, due to congestion of the liver. (4) Studies made with Dr. F. C. Wood in the attempt to correlate location of pain with site of infarct have yielded negative results. (5) The location of pain apparently has some bearing on its quality. The usual terms used in describing the

pain are that it is "constricting" or "viselike," "burning" or "boring." Upper substernal pain is often described as choking rather than constricting. Pain in the upper left chest or back is apt to be burning or boring. Pain in the shoulder, arm or jaw is often described as an intolerable ache. Pain in the precordial region may give a sensation of fulness—as though something had become too large.

One of the differences between angina pectoris and coronary occlusion is that after an attack of angina, the patient is apt to feel very much as he did before except that nervous individuals often suffer from exhaustion as they do following various sorts of experiences; usually, however, during the days following coronary occlusion with myocardial infarction, the patient looks sick, even though his attack of pain had been mild and he has continued working or at least has remained ambulatory.

Fall in blood pressure may be quite prompt or it may be delayed twenty-four or forty-eight hours. The other well-known evidences of infarction such as friction rub, pulmonary congestion, fever, leukocytosis and acceleration of sedimentation rate tend to make their appearance within the first three days.

The diagnosis can be made clinically with a high degree of accuracy in typical cases of acute coronary occlusion with myocardial infarction, particularly after a few days' observation. Many cases, however, are atypical; furthermore, the need for prompt differential diagnosis may be urgent. Under these circumstances, additional evidence is required, and this is furnished by electrocardiography. It is necessary to bear in mind, however, that the diagnosis of coronary occlusion, *per se*, cannot be made from the electrocardiogram. All the tracing can be expected to do is to reflect, more or less imperfectly, the electrical activity incident to the heart beat. Coronary arteries obviously take no direct part in the heart beat, although they supply the blood which makes it possible. Acute disturbances in this blood supply are apt to cause changes in the action currents of the myocardium which are revealed by changes in the electrocardiogram. Thus, the electrocardiogram yields only indirect evidence of coronary occlusion. However, it has been learned that acute myocardial infarction

tends to cause characteristic electrocardiographic patterns which, considered in connection with clinical findings, make the diagnosis of coronary occlusion practically certain. In some cases, however, the findings on the first electrocardiographic examination are inconclusive; under these circumstances, tracings must be repeated. Rapidly changing electrocardiographic patterns, provided extrinsic causes such as drug effects are excluded, reflect rapid changes in the myocardium and may therefore furnish evidence of coronary occlusion even though the complete pattern of infarction does not occur.

During the past five years since we have used chest leads to supplement limb leads in electrocardiography, it has been found that if the clinical picture suggests coronary occlusion with myocardial infarction, and the electrocardiogram fails to confirm the diagnosis either by showing one of the typical patterns or by rapid changes, the clinical diagnosis of infarction is almost certainly incorrect.

Electrocardiography also has considerable value in the diagnosis of the chronic or healed stage of myocardial infarction. This is particularly true of infarction involving the anterior wall of the left ventricle. A pathognomonic electrocardiographic pattern may persist for many years, although it often tends to fade out in time. The chest leads furnish an essential part of this pattern. When infarction occurs in other locations, the electrocardiographic pattern cannot be regarded as pathognomonic, although when considered in relation to the clinical history, it may be helpful in the diagnosis of old infarction.

A problem the practitioner has to face when dealing with a patient in whom he suspects the presence of coronary occlusion, is whether or not to have an electrocardiogram made. There are two reasons to make him hesitate: (1) the expense to the patient, and (2) the possibility that an electrocardiogram may not help in the diagnosis but may actually lead to an incorrect diagnosis.

So far as the expense is concerned, it should cost no more to have an electrocardiogram made than a roentgen ray examination for suspected fracture, and even less if the examination is made at the patient's home. The importance of determining the presence or absence of coronary occlusion is

at least as important as recognizing fracture. Regarding the possibility that an electrocardiogram might actually lead to an incorrect diagnosis, some of the previous discussion is pertinent. There is no valid reason why an electrocardiogram, properly made and interpreted, should obscure the issue. Nevertheless, experienced workers in the field of heart disease not infrequently see cases in which electrocardiography has been responsible for a wrong diagnosis. Such errors are liable to be disastrous.

There are various reasons for incorrect interpretation of electrocardiograms: (1) the technic of taking the tracing may be incorrect. This has been discussed so often that it should not be necessary to repeat it here. It may be pointed out, however, that in taking chest leads, the relative positions of a precordial electrode and the heart itself are important. Most of the work on standardization of tracings has been done with the electrode applied as nearly as possible to the apex. (2) The person interpreting the tracing may not be competent to interpret electrocardiograms. The remedy for this is obvious. (3) There may be failure to take into account all the factors necessary for electrocardiographic diagnosis. This is a far more common source of error than faulty technic or actual incompetence in interpretation. On logical grounds one might contend that electrocardiographic and clinical diagnosis should be completely divorced. There is no reason why the electrocardiographer may not attempt an independent diagnosis as a preliminary procedure, if he so desires. He is on safe ground so far as the recognition of cardiac arrhythmias is concerned and also in cases showing the typical complete pattern of myocardial infarction. However, for adequate interpretation, consideration of all relevant data is essential. It is important to know whether the patient has taken digitalis, and, if so, the details of dosage. Such diverse factors as position of the heart, disturbances of thyroid function, the blood pressure, recent or active infection or debilitating disease or even certain nervous states may be cited as examples of conditions that need to be taken into account. In cases suspected of coronary occlusion, it is particularly important that the entire clinical history should be reviewed so that all possible sources of error of interpretation receive consideration. Furthermore, if the

electrocardiogram does not support a clinical diagnosis of acute coronary occlusion, tracings should be made with an electrode on various parts of the precordium in an effort to detect injury currents. Two or three electrocardiograms a few days apart may be required.

In summary it may be said that the diagnosis of acute coronary occlusion depends first of all on careful history, examination and sometimes repeated observations. Electrocardiograms, including chest leads, should be made in all cases in which the diagnosis cannot be excluded by clinical study. In some cases serial electrocardiograms are required. The interpretation of electrocardiograms should not be relegated to a technician, whether or not he has a medical degree. The tracing should be interpreted with full knowledge of all relevant clinical data available. If these conditions are met, a physician familiar with the manifestations of acute coronary occlusion and conditions which may simulate it should make few mistakes in diagnosis.

**Treatment.**—The first thing to do in an acute attack is to relieve pain if it is severe. Morphine is probably the most effective agent for this purpose, although pantopon or dilaudid may be used. The physician must depend on his judgment as to how much morphine is required. In some cases a single hypodermic injection of  $\frac{1}{6}$  to  $\frac{1}{4}$  grain is adequate. In others, several injections may be required. The use of morphine is sometimes overdone; I have often suspected that the last unnecessary dose precipitated a fatal outcome. One does not need to give enough of the drug to abolish pain completely, although it should be made bearable. Some patients continue to complain but if let alone will promptly drop off to sleep. The application of heat all over the front of the chest is often helpful and may lessen the amount of morphine required.

The patient should be moved as little as necessary during an acute attack. If at home he should stay there unless it is impossible to care for him. He should be placed in bed immediately and, in addition to the use of measures for the relief of pain, he should be kept warm. He should not be annoyed by too many attentions. The illness should not be regarded as a social event calling for the presence of a large gathering of relatives and friends. Nevertheless he should be watched

every moment by a responsible person. Frequent hypodermic injections of supposed cardiac stimulants are very comforting to the family and give them a feeling that something is being done. It would be better for the patient, however, if most of these treatments were distributed among the members of the family who want action. Concentrated glucose solutions by the intravenous route may have some value in relieving pain and helping to support the circulation. It is desirable that further critical study be made of this procedure. Intravenous injections of aminophyllin are recommended by some writers although its value is not yet established. It is said to have been highly effective in relieving pain in certain cases.

The oxygen tent is being used more and more in the treatment of acute coronary occlusion. Oxygen seems to have some value in relieving pain although the results are not spectacular. It is also useful if there is shortness of breath or cyanosis.

Treatment must be individualized not only during the initial stages but thereafter as well. All patients should be kept in bed, but concessions must occasionally be made to those unable to use a bed pan successfully. These patients may be permitted to use a commode by the side of the bed. How long patients should be kept in bed is largely guesswork. Probably those without definite evidence of infarction, or only slight evidence of infarction and favorable clinical course, may be permitted to begin sitting out of bed in four weeks. Some patients must be kept in bed for much longer periods. In such cases the course of the erythrocyte sedimentation rate may be helpful. A return to normal rate may be interpreted as a favorable finding.

The care of the gastro-intestinal tract is important. During the time the patients feel ill, there is usually little disposition to eat heartily. In any event, however, it is well to keep the diet low in bulk and caloric value. Frequent small feedings, 4 to 6 daily, are preferable to normal-sized meals. Distention is often a troublesome feature. It may be treated by the application of heat or turpentine stupes, rectal tube, daily enema, or small doses of salines or castor oil. Drastic purgation or pituitary extracts would better be avoided.

Sleeplessness is often a problem. If it is due to cough, shortness of breath or discomfort in the chest, codeine or a

small dose of morphine is apt to be effective. Otherwise bromides or small doses of barbiturates may be tried.

The question always arises as to whether aminophyllin should be used. Animal experimentation appears to show that it is an effective coronary vasodilator. Furthermore, it has been maintained that myocardial infarction produced in animals by ligating coronary vessels is apt to be less extensive if aminophyllin is given throughout the period of the experiment. These facts afford a logical basis for its use. Nevertheless, considerable experience in giving the drug has thus far failed to convince me that it has much value in the treatment of acute coronary occlusion. Furthermore, some patients do not tolerate it well. The gastric symptoms are well known. It may also cause bladder irritability, restlessness and cardiac palpitation.

Physicians often ask what they should do in the event of sudden collapse of a patient who has suffered coronary occlusion. Sudden collapse may be due to one of a variety of mechanisms. In dogs, sudden death, following ligation of a coronary vessel, is practically always due to ventricular fibrillation; there is reason to believe that this is the most frequent cause of sudden death in patients who have suffered acute coronary occlusion. When ventricular fibrillation occurs, it is probable that events move too quickly for therapeutic action even though any could be effective. Embolism from an intraventricular thrombus or rupture of the infarct may also cause sudden death. However, as is well known, the patient may survive embolism unless it deprives a vital structure of its blood supply. Furthermore, if an infarct ruptures through the intraventricular septum, the patient may survive. These two conditions may, but do not always, cause sudden collapse. The onset of paroxysmal tachycardia, of which the most common is paroxysmal auricular fibrillation, may also cause collapse, particularly in seriously ill patients. However, many patients suffer collapse without any obvious cause except circulatory failure. The value of various restorative procedures in the treatment of sudden circulatory failure is not clearly established. Intramuscular injection of caffeine sodium benzoate and intravenous injections of concentrated glucose solutions at times appear to have some value.

The question of digitalis therapy in the treatment of acute coronary occlusion is frequently raised. There are at least two indications for its use: (1) prolonged paroxysms of auricular fibrillation, and (2) severe heart failure threatening the patient's life. It must be given cautiously since there is reason to believe that full dosage of digitalis is apt to be dangerous. On the other hand, the effect must be prompt if it is to do any good at all. A modification of the Eggleston method, administering half the recommended dosage during the first twenty-four-hour period, may be used. Fortunately, only a small minority of cases require digitalis.

Some observers favor the use of small doses of quinidine two or three times a day in the hope that it will prevent ventricular fibrillation. Its use at the present time is empirical. We do not know with any certainty, whether quinidine will prevent ventricular fibrillation in patients with coronary occlusion, nor if it does, what dosage is necessary or what other undesirable effects it might produce in these very ill patients.

One of the most important duties of the physician is guidance of the patient after allowing him out of bed. The objectives at this time are to do everything possible to help him to recover his strength and to prevent recurrent attacks. The procedures are empirical. It seems sensible to increase activities slowly and well within the limits of the individual's tolerance. He should accept restrictions in his regimen. If he complains about this, one may reply that his former way of living led him into trouble; that if he wants to cooperate in the attempt to avoid further trouble of the same nature, he must live differently. This includes abstemious habits of eating, care of the gastro-intestinal tract, abundant rest and relaxation, and cutting down on work to the point where hurry and the tension that goes with it, are eliminated. There is little knowledge but much difference of opinion regarding the effects of tobacco and alcohol. Under these circumstances, it seems prudent to adopt an attitude of caution. After all, one cannot go far wrong in counseling good habits.

The following points may be made regarding alcohol: while small amounts of alcohol late in the afternoon or before dinner may be useful in certain individuals, it should not be taken before meals by those who have difficulty in curbing

their appetite for food, nor by those in whom it has a tendency to disturb the gastro-intestinal tract. Liberal consumption of alcohol is unwise, if for no other reason than its tendency to make the user relax his regimen in other directions.

There are some statistical data which appear to show that tobacco is of little or no importance as a cause of coronary occlusion. There is no doubt that coronary occlusion may occur in individuals who have used only small amounts of tobacco or none at all. On the other hand, it seems to occur often in those who have been persistently heavy smokers over long periods of time. However, even if a statistically significant relationship could be established, it would not necessarily prove that tobacco had caused the coronary disease or accident. It might be that some underlying nervous or metabolic tendency had been responsible both for the heavy smoking and the arterial disease. However, excessive use of tobacco does cause a tendency to fatigability, increased pulse rate and irritation of respiratory mucous membranes and in some individuals increased nervous tension, disturbance of gastro-intestinal functions and increased consciousness of heart action. Certain patients state that their tendency to attacks of angina pectoris is distinctly less when they do not smoke, although many note no difference whatever. In view of these facts, I think that an attempt should be made to have patients avoid tobacco after an attack of coronary occlusion or at least use it sparingly.

It has seemed to me that in general those patients do best who accept their handicaps philosophically and at the same time lead a careful life, avoiding bad habits and excessive nervous or physical strain. Those who are able to retire from active life and are content to do so, should be encouraged in this course. Those who are unable or unwilling to retire, should review their activities carefully and prune out the non-essentials.

Follow-up studies in patients who have suffered from coronary occlusion show that the liability to recurrent attacks is great and that the expectation of life is far from good. Nevertheless, some individuals do well and are able to carry on for a number of years. It is often helpful to recount instances of such favorable cases to despondent or apprehensive patients and try to encourage them to a more hopeful frame of mind.

## CLINIC OF DR. HENRY K. MOHLER

### JEFFERSON HOSPITAL

---

#### MISSED CARDIAC DIAGNOSIS

CARDIAC disease is difficult to diagnose at times because it has symptoms which are common to many other functional and organic disturbances of the body. Among the disorders resembling heart affections are those arising in the pulmonary, renal, and vascular systems and in the gastro-intestinal and biliary tracts. Dysfunction of the thyroid gland frequently is reflected in disorders of the heart. The increasing morbidity and mortality as a result of cardiac disease constantly are challenges to the medical profession to bear in mind the need for differentiating diseases of the heart from conditions resembling them. Functional diseases of the heart must be separated from organic disease to prevent unnecessarily restricting physical activity where not warranted.

The failure to obtain a detailed history and not infrequently the lack of a complete study of the patient can be responsible for missed diagnoses. Inadequate facilities may account for failure to recognize cardiac disease. A typical history, symptoms, physical findings and an electrocardiogram readily make possible a correct diagnosis of an acute coronary occlusion. The atypical case is one in which a correct diagnosis may be missed.

Signs and symptoms of importance may be transient and often absent at the time of examination. The physician, therefore, lacks possession of sufficient evidence to make a correct diagnosis. Pain in the chest may be incorrectly interpreted as being due to some disease other than of the heart.

Failure to diagnose conditions subsequently proved to be cardiac in origin may prove very disastrous. An attack of acute coronary occlusion allowed to become ambulatory after

the gastro-intestinal features subside may result fatally, because the condition was diagnosed as acute indigestion. In other instances the functional disturbances in the mechanism of the heart may be considered as serious. Numerous restrictions unnecessarily imposed upon the patient, especially as to physical activities, may continue a cardiac neurosis.

It is extremely difficult at times to obtain an accurate description of the character of the pain or abnormal sensations complained of by the patient. Thus is emphasized the importance of continuing at length the discussion of the symptoms as to their character, location, duration and factors bringing on the distress or pain, its relation to effort and rest and whether it comes on during sleep. Pain or discomfort of a serious nature is usually substernal in location and accompanied by dyspnea if it is cardiac in origin.

If this substernal pain is precipitated by effort and is of short duration and is relieved by rest or by the taking of nitrites, the diagnosis of angina pectoris can be made without much doubt and a cardiac diagnosis not missed.

Pain or distress of a similar nature not brought on necessarily by effort, continuous, not relieved promptly by rest, or by the use of nitrites, and associated with shock and dyspnea, must be regarded as probably due to acute occlusion of the coronary artery. Within twenty-four hours this patient will have developed a systemic reaction to the interference with the coronary circulation manifest by an ashen gray color of the skin, the presence of fever, a leukocytosis, a variation in the pulse rate, usually increased (occasionally slow due to an accompanying heart block) with or without an arrhythmia. The systolic blood pressure gradually becomes lower. The presence of these symptoms and signs with a full knowledge of the nature of its onset with the presence of serial electrocardiographic changes in the RST complexes and T and Q waves warrants a definite diagnosis of acute coronary occlusion. The diagnosis may be missed if the patient comes under a physician's care without being given a clear history of what transpired previously—as an example:

M. A., age fifty-four years, longshoreman, brought to the receiving ward of the hospital, giving a rather incoherent his-

tory of having had an attack of grip during the previous week and of being given whisky and quinine to relieve his symptoms, which were cough and general chest pains. The physical examination revealed nothing but the presence of numerous small râles throughout both lungs, but no definite area of consolidation. His temperature was  $101.4^{\circ}$  F., the pulse rate was regular and 100 per minute and the blood pressure 140/100. Albumin and granular casts were present in the urine. The leukocyte count was 11,000. The patient seemed to improve clinically but the fever and the cough continued and two days after admission he died suddenly. Autopsy showed a ruptured heart through an area of infarction of the anterior wall of the heart. The patient was too ill to give a clear history of the onset or attached little importance to the substernal distress, if present at the onset of his illness. The heart during life appeared normal on physical examination.

**Dyspnea**, sudden in onset and gradually improving with rest in bed, may be the only initial important symptom and so overshadow the substernal pain (which if present), was not severe enough to be recognized by the patient. A leukocytosis, an increased pulse rate and a declining previously known high systolic blood pressure may be evidence of an acute coronary artery occlusion.

Nocturnal dyspnea severe enough to cause a patient to sit up in bed to secure relief, accompanied by wheezing sounds in the chest may, unless promptly reported to a physician, be diagnosed bronchial asthma. The symptom-complex of fever, leukocytosis, shock, prostration and ashen gray color of the skin following this nocturnal attack of dyspnea should make one suspicious of the presence of coronary artery occlusion. Dyspnea occurring during the night with hypertension, unless thought of and measures taken to restrict physical and mental activity may be a forerunner of acute coronary occlusion.

**Tachycardia with or without the Presence of Arrhythmia.**—A young adult complaining of tachycardia, with or without evident enlargement of the thyroid gland may be incorrectly diagnosed hyperthyroidism. Two or three basal metabolism tests usually are helpful in determining if the thyroid gland is overactive and hence responsible for the tachycardia. In a number of cardiac patients auricular fibril-

lation may be present, with or without symptoms and signs of congestive heart failure. The increased heart rate as a result of hyperthyroidism often is responsible for the onset of auricular fibrillation. The effective treatment of hyperthyroidism results in slowing of the heart rate and usually normal sinus rhythm returns. The administration of quinidine sulfate is often helpful in restoring a regular rhythm. Should the classical treatment usually effective for the hyperthyroidism fail, one can usually be certain the tachycardia is due to myocardial weakness rather than to an overactive thyroid gland, even though a goiter be present with only a slightly elevated basal metabolic rate.

Tachycardia occurring in paroxysms, sudden in onset, not influenced by posture and sudden in cessation is correctly recognized as simple paroxysmal tachycardia usually not associated with organic heart disease, but may accompany acute coronary occlusion.

The heart rate which is irregular in force, rate and rhythm, becoming increasingly so by effort after showing a pulse deficit in the untreated patient is due to auricular fibrillation.

Premature contractions are responsible for an irregular rate depending on the frequency of their occurrence. They may be recognized at times by their disappearance with exercise and reappearance when heart rate becomes slower. This is not uniformly so, especially if they are associated with organic disease of the heart and hypertension.

A less common occurring tachycardia is sudden in onset, usually associated with marked coronary sclerosis or with acute coronary artery occlusion. This form of rapid heart rate is known as paroxysmal ventricular tachycardia and is recognized by the occasional interruption of the tachycardia by missed beats or a weakness of the heart sounds noticed only by auscultation. The recognition of this arrhythmia is important because the use of quinidine is often effective in causing the condition to disappear.

**Pulmonary Edema.**—Patients may become dyspneic with subsequent cough which quickly becomes productive, frothy and blood-stained and is accompanied by other alarming symptoms. Signs of acute myocardial failure result fatally in a brief space of time from acute pulmonary edema.

These patients on previous occasions may have suffered mild attacks of cough, dyspnea and wheeze to which they paid little attention, believing it to be asthma, but which eventually proved that the left heart failed with an accumulation of edematous fluid in the lungs. Recognition of this possibility will avoid missing cardiac diagnosis.

**Psychoses.**—An active middle-aged patient, without a definite history of substernal distress or pain, presenting a psychosis, sudden in onset, especially if accompanied by symptoms of shock and an ashen gray color of the skin may be the result of a disturbance of the circulation of the blood due to an attack of acute coronary artery occlusion.

The history of previous attacks of substernal pain probably anginal in nature followed by the clinical picture of a psychosis may be shown by electrocardiographic examination to be due to the presence of an acute coronary infarction.

Many of the psychoses give a history of recently having passed through a period of mental shock and strain. Such etiology can be responsible for both conditions and one can readily fail to recognize an attack of coronary occlusion as the real cause and without suitable medical treatment it may terminate in sudden death. Cardiac diseases may be responsible for psychoses.

**Hemiplegia.**—Patients may be ill with the symptom-complex of fever, dyspnea, cyanosis and cough for several weeks and suddenly develop a hemiplegia.

The paralysis may be the result of an acute coronary artery occlusion with the mural clot over the area of infarction forming a source of emboli. The absence of typical signs and symptoms of recent infarction of the myocardium may mislead one.

As to the correct diagnosis, until the hemiplegia occurs the possible etiologic factor may be overlooked.

**Pericarditis.**—The presence of the symptom-complex of fever with signs of a pericarditis in an elderly person always should make one suspect the presence of acute coronary artery occlusion being the underlying cause. The symptoms and signs may be typical in character and if the infarction involves the diaphragmatic surface of the heart the pain may be of the shoulder top type. Pain in the shoulder should not be treated

as a local process without considering the possibility of it being cardiac in origin.

**Hemoptysis.**—Not infrequently blood spitting accompanies cardiac lesions as the result of passive congestion of the lungs. Many of the infective processes, neoplasms and ulcerative conditions in the lungs are associated with dyspnea, chest pains and cough. The possibility of blood spitting being cardiac as well as pulmonary in origin calls for a very careful investigation of the heart which otherwise may result in incorrectly attributing the blood spitting to a lung lesion in the presence of congestive heart failure as the result of mitral valve damage.

The pulmonary lesions when tuberculous in origin are commonly located at the apices of the lungs. Areas of bronchiectasis may be found in any location in the lungs but not infrequently they are located at the bases, the distribution of the lesion being similar to those found in congestive heart failure.

Hemoptysis in the presence of a well-defined presystolic murmur and thrill in the mitral area practically excludes active pulmonary tuberculosis.

**Ascites with a Heart Murmur Present.**—The presence of ascites and valvular lesions of the heart are not necessarily the result of congestive heart failure. A young married woman, twenty-four years of age, noticed her abdomen gradually increasing in size. She consulted a physician who, upon examination, found her lungs clear and resonant throughout, the area of cardiac dulness was normal in outline and a presystolic thrill and murmur were present in the mitral area. The heart sounds occurred regularly and were of good quality. The liver could not be definitely outlined due to the presence of considerable amount of ascites. Slight pretibial edema was present. The blood pressure was 120/80, temperature 99.6° F., the respirations 26 per minute and the radial pulse 76 per minute. The patient was more comfortable lying flat on her back than sitting up. This observation with the normal lungs, heart rate and rhythm, with the presence of fever, by a process of elimination it was thought that the cause of the ascites and other signs and symptoms would be found in the abdomen. A small central incision under local anesthesia was made by a

surgeon, relieved the ascites and revealed the presence of widespread miliary tuberculosis of the peritoneum. With proper convalescence obtained for the patient her health was restored and she has enjoyed excellent health with the mitral lesion present and well compensated for, since 1921.

**Pulmonary Embolism.**—The slowing of the circulation in patients following long confinement to bed, postoperatively, in the treatment of fractures of the neck of femur or vertebrae and in chronic illness, may result in phlebitis occurring in previously varicose veins or in apparently normal veins. From these inflamed veins oftentimes clots are liberated and act as emboli passing through the right heart into the pulmonary artery and its branches. If the clot is of sufficient size death may occur immediately. At other times clots smaller in size, not sufficient in size to occlude the larger branches of the pulmonary artery, may lodge in the substernal region. The symptoms of shock with cyanosis and substernal pain make up this clinical picture. The symptomatology and signs may thus be very similar, early in the course of pulmonary embolism and acute coronary artery occlusion, but within twenty-four hours in the pulmonary embolism, if the patient survives, cough, expectoration, usually frothy and blood-tinged, occurs with continued degree of cyanosis and distention of the veins of the neck.

Electrocardiographic changes of myocardial weakness are present in both conditions but typical electrocardiographic findings are never present in pulmonary embolism, important early in the making of the correct diagnosis of coronary thrombosis.

**Paroxysmal Attacks of Pain in One or Both Arms.**—Neuritis-like pains in the left arm or both arms not necessarily referred from the substernal or precordial region. The referred pain experienced in the left arm only, the right arm only, or to both arms is so well known in association with an attack of angina pectoris or acute coronary artery occlusion as to require little comment.

The occurrence of this pain in both arms severe enough to awaken the patient from his sleep during the night with all symptoms of shock present, and requiring two hypodermic injections of morphine sulfate  $\frac{1}{4}$  grain at half-hour intervals

to afford relief, subsequently was proved to be due to an attack of acute coronary artery occlusion. Substernal distress was not severe enough to attract attention, nevertheless the diagnosis of acute coronary occlusion could have been readily overlooked but for serial electrocardiographic examinations. Although many instances of paroxysms of pain in the arms are not severe enough to produce shock with or without substernal distress and dyspnea, its presence in an individual more than forty years of age should be regarded as suspicious (possibly associated with coronary artery disease) until excluded by clinical observation and electrocardiographic examination.

**Convulsions and Temporary Loss of Consciousness.—**

Numerous instances of generalized convulsive seizures may occur in patients and be incorrectly diagnosed as to the etiology. These attacks may have been reported to a physician without the latter having had an opportunity actually to observe them. A diagnosis of epilepsy frequently has been made because the examination of the heart between attacks proved normal. An opportunity to observe the patient during an attack or an electrocardiographic study at that time may have revealed ventricular standstill, a prolonged PR interval, complete heart block or the special manifestation of heart block described as Adams-Stokes syndrome. Unless the physician has observed the attack and noted the condition of the circulation during the convulsion he is not warranted in making a final diagnosis of epilepsy. It is important to exclude every form of heart block with its resulting anoxemia by an electrocardiographic study before an etiologic diagnosis is made of any convulsive seizure or loss of consciousness.

Acute indigestion has been a term that has frequently masked underlying cardiac pathology. Considerable attention has been directed to the differential diagnosis between acute coronary occlusion and an acute surgical or medical condition in the abdomen. Ruptured peptic ulcer, gangrenous gallbladder or gallstones or renal colic, acute pancreatitis, acute appendicitis, acute lead poisoning, crisis of locomotor ataxia have been incorrectly diagnosed when the subsequent course of events proved the condition to be due to acute coronary occlusion.

Of importance is a previous history of similar attacks of

heart pain associated with various degrees of shock, an ashen gray color of the skin rather than pallor. In coronary occlusion the distress is usually beneath the sternum and in conditions arising in the abdomen the location of the distress is lower, even though in the epigastrium. Epigastric pain is not referred to the arms such as may be pain cardiac in origin.

**Subacute Bacterial Endocarditis.**—The very first symptom or physical sign resulting eventually in the diagnosis of subacute bacterial endocarditis may be an embolic phenomenon, such as in central retinal artery causing partial blindness, in the brain causing interference of the function centrally controlled in the area in which the embolism lodged. The pain over the splenic area may be traced to an embolism lodging in the spleen. The subacute arthritis may be the outstanding symptom of a subsequently recognized subacute bacterial endocarditis.

The findings upon examination of the urine of the presence of blood, albumin and casts may be discovered to be due ultimately to emboli lodging in the kidney from subacute bacterial endocarditis.

Fever-free stages as well as bacteria-free periods in the course of subacute bacterial endocarditis may temporarily delay the recognition of the presence of subacute bacterial endocarditis. The fact that this may occur should be of assistance in recognizing heart conditions, which otherwise can readily be missed.

FROM THE DEPARTMENT OF DERMATOLOGY AND SYPHILOLOGY,  
SCHOOL OF MEDICINE, UNIVERSITY OF PENNSYLVANIA, AND  
THE SYPHILIS CLINIC OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

---

### THE DIAGNOSIS AND TREATMENT OF SYPHILITIC AORTITIS

THE best work in the field of syphilitic cardiovascular disease is done by the combined effort of cardiologists and syphilologists, rather than by either alone. The average practitioner, despite his inevitable and constant contact with the field of syphilis, flounders helplessly in the morass of technic and technicalities which the field of cardiovascular syphilis of necessity involves. The internist, hyperacute toward one or another aspect of the confusion border line, has been shown repeatedly by autopsy evidence<sup>1</sup> to have perished ignominiously between the diagnostic hay-bales of rheumatic aortic disease and syphilitic aortic disease. It would therefore be both unseemly and indiscreet for us not to credential ourselves in presenting this subject by reference to F. A. Willius and to C. G. Wolferth, who though they have not directly participated in the present discussion, have contributed at least alternate vertebrae in its backbone by supplying the fundamental expert knowledge of the pathologic physiology of the heart and aorta, and the physical diagnostic proficiency necessary to the weighing of the difficult questions which so constantly arise in the individual case. The roentgenology of the field is now sufficiently at the command of the cardiologist to make him a preferred referee for this part of individual case study; for the cardiologist's knowledge of the functional behavior of

the aorta, as depicted in the movements of the shadow, is at least fully as important as the mere mensural estimation of the shadow itself.

The problem of uncomplicated syphilitic aortitis, if it is to be recognized in the uncomplicated stage, is as difficult as it is critical. Too much emphasis cannot be placed on the statement that when a regurgitant aortic lesion, a hugely dilated heart, or a pulsating aneurysm is identified, somebody has fallen down on his job. For that reason, and because it is so fundamentally important that we drill ourselves constantly in the preventive outlook toward syphilitic cardiovascular disease, little is said in this presentation about the treatment of advanced and consequential syphilitic lesions of the heart and aorta. They constitute, we hope, the medicine of a passing, rather than a future generation.

A discussion of diagnosis and treatment in this field needs a minimal statistical background. It can be drawn almost entirely from two sources, with a third we hope to be added in the not-far-distant future. Bruusgaard<sup>2</sup> has, subject to certain inevitable limitations of material and method, portrayed quite clearly the biologic course of untreated syphilis with respect to the cardiovascular system in man. This form of involvement was not recognizable in untreated living patients within the three- to ten-year observation period, dating from onset of infection; appeared in only 1.5 per cent in the ten- to twenty-year group; sprang into recognition to the extent of 10 per cent in the twenty- to thirty-year group, and 12.5 per cent in the thirty- to forty-year group. Bruusgaard's methods, painstaking though they were, could not avail themselves fully of criteria of diagnosis which recent work by roentgenologists, cardiologists, internists and syphilologists has tended to emphasize. Granting to our newer material a reasonable though not as yet exactly determined validity, it appears, using the figures of the Cooperative Clinical Group<sup>3</sup> embracing 907 American patients receiving any and every form of treatment used by the investigators, that from 1916 to 1931, 0.7 per cent developed outright cardiovascular syphilis in the three- to ten-year period after infection; while 1.3 per cent developed a suspicious sign in the form of dilated aorta. In the ten- to twenty-year period 5.8 per cent of the patients

developed definite aortitis, and 4.6 per cent additional were open to suspicion. The difference between 10.4 in the Co-operative Clinical Group series and Bruusgaard's 1.5 per cent of aortic change or involvement represents possibly, though improbably, an advance in time of onset of syphilitic aortic disease under modern conditions of treatment. Far more probably, however, it represents the effect of employing for diagnosis physical and roentgenologic criteria which Bruusgaard did not use. Thus, despite Langer's<sup>4</sup> debatable contention of premature onset and the unsettled question as to whether our present criteria for early diagnosis genuinely represent the onset of syphilitic as distinguished from other forms of aortitis, we find ourselves obliged to use, for lack of anything better at the moment, a group of diagnostic symptoms and signs presently to be given that may prove, within the next several years, to have been the hotly controversial, rather than the coldly rational end of the diagnostic poker. Such a contingency we must accept with what grace and humility we can.

**The Pathologic Physiology of Syphilitic Aortic Disease.**—One is materially assisted toward an understanding both of the possibilities and the perplexities of diagnosis in the preventive period of syphilitic great vessel disease by an informal review of the pathology. There are a number of reasons for describing the syphilitic involvement of the aorta as a periaortitis and mesaortitis, the former as the probable initial phase.<sup>5, 6</sup> The more closely one studies roentgenologically and symptomatically the phenomena associated with therapeutic testing and clinical improvement in aortic syphilis with relief of symptoms accompanied by paradoxical increase of signs, the more is one led toward the belief that an inflammatory process in the mediastinal tissue around the aorta, quite as much as one within its wall, is essential to the explanation of much of the symptomatology and diagnostic signs.

The inflammatory changes in and about the aorta achieve their importance not only through their effect as such on the vessel wall, but through their location with respect to the heart.<sup>7</sup> The nearer the infiltrative process is to the aortic ring, the graver is the situation of the patient and the more certain is the development of regurgitation and of myocardial, by way of coronary, injury in the individual case. On the other

hand, the higher up the ascending portion of the aorta or the arch itself is involved, the more probable is the development of aneurysmal change through the effect of an intact aortic valve in maintaining diastolic pressure against a weakened vessel wall.<sup>6</sup> Thus it comes about that disease of the root of the aorta is in general of graver prognosis, granted an approximately equal date of recognition, than is disease of the upper ascending or arciform portion of the aorta. In general aneurysm, reasonably early discovered, is not incompatible with long and effective life. Disease of the bulb, however, with its involvement of valve cusps and coronary orifices, has a profound element of unpredictability and may, despite every therapeutic precaution, be found to eventuate in serious structural damage followed by marked limitation of working capacity and an easy transition into dilatation, breach of compensation and myocardial damage.

The roentgenology of early aortic disease, whether arteriosclerotic, rheumatic or syphilitic, owes much of its differential interpretation to the foregoing considerations. The increase in density of the aortic shadow can be recognized in both arteriosclerosis and in syphilitic aortitis. The age factor seems frequently to be invoked to distinguish the two. Apparently the arteriosclerotic type of change, with its tendency to calcification, less likely to occur in the syphilitic aorta,<sup>8</sup> leads to a wider, denser but more rigid tube than does the syphilitic inflammatory infiltrate with the weakened fibrotic wall to which it gives rise. Dilatation, with increased pulsation, together with an increase in density out of proportion to the patient's arteriosclerotic age expectancy, suggests, therefore, though it does not alone establish, a syphilitic type of pathologic process.<sup>9, 10, 11</sup> This we take to be the gist of the discussions which have marked consultation reports of cardiologists who personally examine with the fluoroscope the aortas of patients we have referred to them with the syphilitic differential problem in mind.

As in the roentgenology, so in the physical diagnosis; the pathologic physiology of aortitis, syphilitic or otherwise, makes rational the critical findings on physical examination which act as suspicion arousers and guides to ultimate diagnosis. Again, the higher in the ascending aorta the involvement reaches its

maximum, the fewer will be the early symptoms of which the patient complains. The symptomatology of early syphilitic aortitis is more apt to be symptomatology of the bulb. The sense of precordial stress, anginoid pain, actual anginal seizures, dyspneic storms, especially nocturnal, and the signs of failing heart, are in the main expressions or sequelae of bulbar aortic disease. Aneurysms present, in place of the symptoms and signs of cardiac embarrassment, the rather late-appearing earmarks of localized pressure—pain and the malfunction of special structures within the thorax. It is not suggested that the two processes are mutually exclusive, but in the main it is probably true that disease of the bulb with the breakdown of the valve is what saves the patient from aneurysm, only to bring him to an earlier death by the circulatory load thrown back upon an impaired heart.

The physical signs of aortitis and especially of syphilitic aortitis are easier to remember if one keeps the pathologic physiology in mind. Accentuation of the aortic second sound, as compared with the pulmonic, and a definite tonal change in its quality, is perhaps also expressive not of damage to the valve so much as change in the vessel wall, both in rigidity and texture, as in the case of the murmur according to experiments such as those of Reid.<sup>12</sup> Just what it is that makes the difference between the flat accentuation of the aortic second sound in arteriosclerosis, as distinguished from the hollow, drumlike tambour quality of the aortic second sound in syphilitic aortitis, pathologic physiology and autopsy observation do not as yet disclose. The question as to whether the clinical differentiation of these two tonal qualities rests on valid observation, no mere syphilologist can undertake to answer, but the consensus of cardiologic opinion concerned with syphilitic aortitis is that the tambour or drumlike change in quality has definite significance for syphilitic origin.

When it comes to the interpretation of murmurs, as distinguished from tonal quality, one enters a far less clearly illumined field. The chronologically initial systolic aortic murmur representing changes in valve or wall is indeed of most uncertain etiologic significance. Among the murmurs at the base of the heart it may all too easily, if taken alone, lead to serious diagnostic misinterpretation. That it can be a product

of arteriosclerotic change is undeniable. That it can equally well be produced by syphilis is equally undeniable. The stand apparently taken by many practicing physicians that no interpretation can be placed on such a murmur until it is accompanied by the diastolic murmur of regurgitation or by an Austin-Flint is, however, pressing the issue to the point where preventive considerations are forced to yield entirely to an academic diagnostic dispute. If one is to wait for diagnosis until regurgitation develops in a syphilitic aortitis, he has waited too long.

The weighing of the arteriosclerotic against the syphilitic factor in the interpretation of an aortic systolic murmur is not unlike the weighing of density and pulsation changes under the fluoroscope. Age factors, the general arterial tension and state, the tonal quality of the second aortic sound, variations produced by position, especially intensification on leaning forward, and above all the recurrence, time after time in physical examination, of essentially the same group of signs, would seem to us to have more importance in the diagnostic evaluation than the mere systolic timing of the murmur as such.

All interpretations of early signs of syphilitic aortic disease involve an appraisal of concomitant and collateral manifestations in the patient.<sup>13</sup> Thus again youth, for example, when accompanied by evidence of premature cerebral vascular disease for which there appears to be no familial and no essential hypertensive basis, increases the presumption of syphilis. Familiarity with the various clinical pictures of neurosyphilis and a pushing of the routine medical work-up of a doubtful case to the point of examining the spinal fluid, may not infrequently assist in attaching the aortic picture by inference directly to a syphilitic etiology. On the other hand it is quite as necessary to be familiar with collateral arteriosclerotic manifestations in the nervous system. It is important, too, to realize that time is not the only thing which brings arteriosclerosis as distinguished from active syphilitic inflammatory disease of the vessels into operation in a given case. Arteriosclerosis is possible in comparatively young persons and arteriosclerotic change is a reasonably expected, though uncertainly frequent, accompaniment of syphilitic as it is of many chronic infective processes. The gradual development, therefore, of

hypertension in a younger individual, particularly a rise in his diastolic pressure, when one knows that he has had syphilis. creates a double rather than a single or solely arteriosclerotic anxiety in his behalf. On the other hand, the appearance in the third and fourth decades of clear-cut evidence of cerebral arteriosclerosis, for example, only throws a strong presumption toward arteriosclerosis as the explanation of aortic signs. It does not establish it absolutely nor absolutely eliminate syphilis.

The problem of acute rheumatic fever as a factor in aortic inflammatory disease is far from evaluated. T. B. Mallory's<sup>5</sup> exposition of the characteristic pathologic changes in the aortic valve cusps of syphilis, and his insistence that they are impossible in rheumatic endocarditis with stenosis, does not take us quite far enough clinically to throw the rheumatic fever factor out merely on the demonstration of aortic regurgitation. But as syphilologists we have long taken and still do take the stand that given an aortic lesion in a patient, who, though seronegative on the blood at the time of examination, and with a history suggesting rheumatic fever, has a fair presumptive background for a syphilitic infection, presumptive acceptance of syphilis as an element in his aortic picture is not only justifiable but wise. As a practical issue the differentiation of rheumatic and syphilitic factors in an aortitis is, we believe, to be dealt with by the suitably performed therapeutic test<sup>14a</sup> rather than by the gesture of dismissal of the syphilitic possibility which it too often receives.

It sharpens the edge of early diagnosis again to recall the "too late" or consequential manifestations of uncomplicated syphilitic aortitis. They belong practically entirely in the domain of the slowly crippling, the irremediable and the fatal. Coronary disease has become almost inevitable in the patient whose aortic sinuses are once thoroughly scarred by an unidentified syphilitic process. Myocardial damage is inevitable in the large proportion of patients who have sustained coronary occlusion and fibrosis. Breach of compensation in the syphilitic patient is often of sudden onset and, as has been repeatedly pointed out, of grave prognostic significance.<sup>15</sup> So important is the first breach in the life expectancy of syphilitic aortic disease, that a wringing of hands is an entirely appropriate

gesture at the bedside of any puffing and panting patient whose syphilitic aortitis has, through disregard of early, even though sometimes controversial signs, been permitted to progress to actual breach. Aneurysm is the essentially stealthy member of the consequential quartet. Unless it is fortunately situated where it gives rise to a sharp and concrete pressure symptomatology it may progress to the point of hopelessness absolutely unrecognized.

We are now ready for the list of early diagnostic signs and symptoms which we quote, with some commentary of our own, from the Cooperative Clinical Group's<sup>15</sup> recent summary. The items are given in order of diagnostic importance.

- I. Teleroentgenographic and fluoroscopic evidence of aortic dilatation.
- II. A tympanitic, bell-like, tambour accentuation of the aortic second sound.
- III. A history of circulatory embarrassment.
- IV. Increased retromanubrial dulness.
- V. Progressive cardiac failure.
- VI. Substernal pain.
- VII. Paroxysmal dyspnea.

In the fluoroscopy the pulsation seems to rate at least as high as does the widening of the aorta. Increased density, while less specific, is often observed. Increased density, out of proportion to age and general arteriosclerotic signs, is suggestive but not diagnostic.

In the interpretation of the aortic second sound, in relation to hypertension and arteriosclerosis, the blood pressure should be taken more than once, and the patient's mind be set at rest regarding the procedure. The second examination, a day following that on which the first study is made, not infrequently reduces the importance of an apparent hypertension element very considerably. The rise in diastolic pressure, if maintained, is more significant than a high systolic pressure, and more suggestive of arteriosclerotic change than of uncomplicated syphilitic aortitis.

Inspection of every patient should include a keen glance at the "total person"—an appraisal of his mental and muscular tension, his facies as an indicator of his neurogenous substrate, his account of work, play, responsibility and problems as a

guide to his functional reactivity and neurocirculatory instability. Yet the disposition to rate a sign or situation as "functional" must be sharply controlled, especially in physician-patients. The cardiac impulse over the chest and above the clavicle with the patient fully at rest often is a revealing observational trifle. A wide heaving lift, even though of small excursion, to the left side of the thorax, a heavy wave running upward into the neck as the resting patient lies quietly before one, is a significant item, often adding great weight to otherwise slight murmurs and insignificant enlargement, in the estimation of circulatory organic as against functional disease.

Both in the interpretation of the foregoing findings, and in the interpretation of murmurs over the aortic area and the heart base, a previous knowledge of the patient's status is one of the most valuable aids. This is indeed one of the best reasons why a patient who acquires the disease should, if possible, early be placed under expert central supervisory direction and receive within the first five years the benefit of cardiologic consultation. To have become familiar with the sounds made by a given heart and great vessels over a period of years is one of the best assurances one can have that an interpretation of a pathologic state, if and when it develops, will be soundly and promptly made. In every case it is essential to approach the examination not casually, but searchingly and yet nonetheless with no disposition to read into essentially small or transient items a crucial and exaggerated significance.

The symptomatology of syphilitic cardiovascular disease, as given in the list is, in our estimation, late rather than early stuff. Diagnosis deferred until progressive cardiac failure appears; until substernal pain is clear-cut, not to say marked; and until the patient has developed the asthmatic nocturnal seizures designated as paroxysmal dyspnea is made so close to the border line of lasting damage and incapacity that prevention becomes an academic rather than a real issue.

**The Serologic Tests.**—The student of syphilitic cardiovascular disease two decades ago found himself hamstrung by the inadequacies and uncertain interpretations attaching to blood Wassermann tests. The expectancy of a positive result in aortic disease of syphilitic origin and the gradient of increasing sensitiveness combined with specificity which has marked

gesture at the bedside of any puffing and panting patient whose syphilitic aortitis has, through disregard of early, even though sometimes controversial signs, been permitted to progress to actual breach. Aneurysm is the essentially stealthy member of the consequential quartet. Unless it is fortunately situated where it gives rise to a sharp and concrete pressure symptomatology it may progress to the point of hopelessness absolutely unrecognized.

We are now ready for the list of early diagnostic signs and symptoms which we quote, with some commentary of our own, from the Cooperative Clinical Group's<sup>15</sup> recent summary. The items are given in order of diagnostic importance.

The symptomatology of syphilitic cardiovascular disease, as given in the list is, in our estimation, late rather than early stuff. Diagnosis deferred until progressive cardiac failure appears; until substernal pain is clear-cut, not to say marked; and until the patient has developed the asthmatic nocturnal seizures designated as paroxysmal dyspnea is made so close to the border line of lasting damage and incapacity that prevention becomes an academic rather than a real issue.

**The Serologic Tests.**—The student of syphilitic cardiovascular disease two decades ago found himself hamstrung by the inadequacies and uncertain interpretations attaching to blood Wassermann tests. The expectancy of a positive result in aortic disease of syphilitic origin and the gradient of increasing sensitiveness combined with specificity which has marked

the advance of serologic technic in syphilis is well represented by the following successive figures. In the Mayo Clinic series considered by one of us,<sup>14b</sup> no case of which postdates 1923, only 57.5 per cent showed strongly positive Wassermann reactions on the first test. By repetition and provocative procedures, this proportion was raised, however, to something short of 70 per cent. In Moore, Danglade and Reisinger's<sup>1</sup> survey of Johns Hopkins experience 75.3 per cent positives were obtained. Carter and Baker,<sup>10</sup> from the same institution, reported 92.6 per cent positives in their first 100 cases. Miller,<sup>17</sup> on our service at the University of Pennsylvania, obtained 81.8 per cent positive Kahn tests, and 84.8 per cent positive Kline tests. Prior to 1924, Elliott<sup>8</sup> had placed the margin of error of the negative blood Wassermann reaction in syphilitic vascular disease as high as 40 per cent. It has now dropped to 20 to 25 per cent and positive expectancy has ranged from 75 to 80 per cent. Since much syphilis recognized today has at one time or another in its life history received treatment for the disease, the Cooperative Clinical Group's<sup>15</sup> figures are useful. Of those patients with syphilis who had received no treatment or an unknown amount prior to recognition of the uncomplicated syphilitic aortitis, 83 per cent had a positive blood Wassermann reaction at the time the cardiovascular diagnosis was made. If more than 18 injections of an arsenical, with interim heavy metal, had been given prior to the detection of the uncomplicated syphilitic aortitis, the percentage of positive blood Wassermann reactions had dropped to 52.

While it will thus be apparent that serologic criteria in the diagnosis of syphilitic aortitis are of a variable and frequently uninterpretable uncertainty, the routine performance of serologic tests for syphilis as part of every medical examination will extend the range of our inquiry and recognition of superficially symptomless "latency." If therewith there can be developed an increase in the suspicion with which the syphilitic's heart and aorta are regarded and a willingness to treat, on that suspicion, the reasonable possibility of syphilis, we shall have the essentials of what one might call "late prevention."

The association of cardiovascular syphilis and neurosyphilis has been alluded to and has significant diagnostic

value. The Cooperative Clinical material,<sup>15</sup> which represents the latest expression on this matter, showed that 49 per cent of 191 cases of uncomplicated syphilitic aortitis receiving lumbar puncture within one month of the detection of the great vessel involvement showed unquestionable spinal fluid abnormality. It is not necessary, however, to press the matter to the point of lumbar puncture in every case. Close attention to pupils and reflexes, to the differentiation of pin-point and touch and of vibration sense, together with a carefully taken history, particularly of lightning pains, will often lead to a fairly convincing corroborative finding of syphilitic central nervous system involvement. In the presence of such signs, a negative blood and spinal fluid does not in itself exclude syphilis.

One more point in diagnostic technic in our opinion deserves emphasis. There is in diagnosis, as in therapeutics, a disposition to apply one's procedures seriatim rather than simultaneously to the evaluation of problems, too often allowing a case to stand under a negative finding, or to lapse when more persistence and completeness would have supported a judgment. In the field of cardiovascular syphilis we believe this to be a serious mistake. The appraisal of a patient for the diagnosis of syphilitic cardiovascular disease should not be made by serologic test or by physical examination alone, followed after a year or two by an electrocardiogram, and then subsequently by fluoroscopic or other study. The procedure in its entirety, and the syphilologic examination complete, coupled with a painstaking medical history, is not too much to employ in a consultative session, in the effort to detect and interpret the individual status with reference to syphilitic cardiovascular disease.

#### THE TREATMENT OF SYPHILITIC CARDIOVASCULAR DISEASE

**Prevention of Uncomplicated Syphilitic Aortitis.**—The last decade has brought several advances in knowledge of the treatment of syphilitic cardiovascular disease. The statistical evaluations of the American Cooperative Clinical Group and the United States Public Health Service, while they do not yet cover the twenty- to thirty- and thirty- to forty-year periods after infection, have established a strong presumption that the

use of adequate treatment for early syphilis with arsphenamine and bismuth has high preventive efficiency in controlling late syphilitic aortitis. The whole problem is of course complicated, as internists and cardiologists have not hesitated very properly to point out, by the small numbers of patients in the higher duration brackets of the material thus far assembled, and by the fact that it is still undecided what part if any of an aortitis in a given syphilitic patient is syphilitic and what part of it is aortitis of some other description, including even perhaps therapeutically induced damage by chronic heavy metal and arsenical intoxication.

We must accept for the moment these criticisms of present knowledge; and in doing so simply quote you in summary form the experience of the Cooperative Clinical Group.<sup>15</sup> Their terminology rates 20 arsphenamine injections, with the appropriate interim heavy metal treatment between arsenical courses, as adequate treatment. Of 318 patients with early syphilis, of whom 199 were observed from three to ten years, 41 from ten to twenty years, and 2 twenty years and over, only 5 patients developed uncomplicated syphilitic aortitis. Of 1226 patients receiving adequate regular treatment (equal to or in excess of the above described standard), only 2 developed uncomplicated syphilitic aortitis. The observation periods for this second group were, however, less than three years in 893, from three to ten years in 323, and from ten to twenty years in 10 cases.

Bruusgaard's<sup>2</sup> follow-up study showed 1 death per 100 with cardiovascular involvement in untreated syphilis, while the Cooperative Clinical Group series showed 1 death in 500 in the three- to ten-year period among its treated cases. Bruusgaard had 10 deaths per 100 with cardiovascular syphilis in the ten- to twenty-year untreated group, while the Cooperative Clinical Group had no deaths in 88 treated cases of the same duration.

Let us at least, while conceding the shortcomings of this statistical material, draw a certain amount of hope and encouragement from it. No one who has any considerable experience with syphilis through the life course of the infection is prepared to expect of any form of treatment an absolute control of syphilitic aortic disease. It does progress at times

in the face of negative serologic findings precisely as does vascular syphilis of the nervous system. It progresses, too, in spite of treatment which admittedly, however, is employed too late and after the process must have become well established and capable of crippling functional effect, even though stopped in its tracks at a given grade of damage. That large group of patients, likely to be larger in the future, who are recognized in latency by the findings of positive serologic tests for syphilis, as studied by Moore<sup>18</sup> for the Cooperative Clinical Group series, was found to present cardiovascular relapse or progression to some form of roentgenologically or clinically recognizable lesion in 1.6 per cent of cases.

Systematized preventive or "curative" treatment of early syphilis, intended to do away as far as possible with the manifestations of late syphilis, resolves itself at the present time into a choice between the two standard systems of treatment endorsed by the League of Nations Commission<sup>19</sup> which has had this problem under study for nearly a decade—the British-Danish intermittent and the American continuous alternating systems. With their universal adoption syphilologists at least are disposed to believe that an almost negligible residue of syphilis of the cardiovascular and nervous systems will remain to be dealt with in our patients' later lives. In fact the reexaminations after periods up to ten years of patients treated by either an ideal American sixty-five weeks' continuous or a twenty-one months' American type intermittent system, as currently in process of evaluation in this country, reduces all forms of progression of the disease, significant and nonsignificant, to 8 to 10 manifestations per 100 cases, including serologic relapse. Under ideal continuous treatment no cardiovascular complication has thus far appeared. Under ideal intermittent treatment, 0.7 per cent of patients developed cardiovascular progression and under irregular treatment 0.9 per cent.

The distinctive features of the American alternating continuous system of treatment for early syphilis are:

- (A) The complete absence of rest intervals, purposeful or otherwise, at least during the arsphenamine-heavy metal phase.
- (B) A duration or prolongation of treatment to a full sixty-five weeks—or, failing that, every effort to keep the treatment continuous for at least the first six to eight months.

(C) The administration of 32 adequate doses of an arsphenamine (or neoarsphenamine) intravenously (0.45 to 0.75 Gm. "914") with weekly intervals between injections in courses of not less than 8 injections for the first and 6 for the second, third, fourth and fifth courses. The arsenical courses alternate with courses of weekly intramuscular injections of not less than 0.2 Gm. bismuth salicylate or its insoluble equivalent to a total of 60 intramuscular injections. The earlier alternating bismuth courses may be of 4 to 6 injections each. Upon the completion of the arsenical phase of the treatment, the bismuth courses may be lengthened to 10 or 12 injections each, separated for the first time by complete rest intervals of eight to ten weeks, provided the spinal fluid has been negative before the first rest period is begun.

For the many patients who come to us in latency with only positive serologic tests to prove the existence of their infection, a technic of treatment for latency has been proposed on the basis of the Cooperative Clinical Group evaluation of this phase of the disease. It should be recalled that this system aims more at the prevention of future disability and the stopping of progression than it does at mere serologic reversal. This Cooperative Clinical Group<sup>18</sup> system for latency of more than four years' duration consists of 24 injections of an arsphenamine, given in 3 courses in alternation with heavy metal (preferably bismuth) without rest intervals until after the arsenical phase is completed. Subsequent prolongation of the heavy metal therapy varies somewhat with the individual factors, but in general this phase of the treatment should be prolonged (about one to two years) with rest periods of eight to ten weeks between bismuth courses of 10 to 12 injections after the arsphenamine phase is over. Yearly courses of bismuth in succeeding years up to three, five or even ten are commended.

**The Treatment of Recognized Syphilitic Aortitis.**—So much then for preventive treatment before the development of outspoken, clear-cut signs of syphilitic aortitis. Once these have developed we confront on the one hand inadequate and insufficient treatment for the syphilitic factor in the cardiovascular picture, and on the other, as Scylla to Charybdis, excessive and ill-judged treatment for syphilis at the expense of injury to the aorta and heart by therapeutic shock and

therapeutic paradox. In the last ten years it has been interesting to watch how the set-back of discovering that we were killing patients in the process of "curing" them of cardiovascular symptoms and signs, has gradually given way to a more hopeful reaction and a renewed boldness in the use of the arsenicals particularly in the treatment of uncomplicated syphilitic aortitis. Most of the damage done in the 1910's to 1920's by the brash and excessive use of the arsenicals arose from the fact that these drugs, with their excessively rapid healing effect, were used on advanced cases and cardiovascular wrecks rather than on patients in the earliest stages of aortic involvement. Under such undifferentiated treatment, therapeutic shock killed some patients with aneurysm within forty-eight hours after the first injection of a full dose of "606" or "914," and relieved other patients for a month or two of their anginal symptoms only to have them perish miserably of an uncompensated healing sclerosis of their syphilitically involved aortic bulbs and coronary orifices. Such unintended misuse of modern treatment for syphilis should now be an affair of the past. A safe approach to the treatment of syphilitic aortitis with the avoidance of therapeutic shock and paradox can be made today either by the preliminary use, over a period of weeks, but more often of months, of a heavy metal and iodide before the arsenical treatment is begun. A second method, long in use, consists of the employment from the outset of an exceedingly small but ascending dose of an arsenical or a combined arsenical and heavy metal (as in bismuth arsphenamine sulfonate) over a long period.

The question of selection of a heavy metal for preparatory treatment, with a choice between bismuth and mercury, cannot in our opinion be regarded as wholly settled. Bismuth is a faster-acting drug than is generally realized, and is enough like an arsphenamine in its action so that it is wiser to use very small and more frequent doses of a rapidly absorbed and rapidly eliminated salt, such as the water-soluble sodium bismuth tartrate, than it is to use the large doses of some of the insolubles applicable to the treatment of other phases of late syphilis. Even with such precaution one is occasionally seriously disturbed by evidences of early strain on compensation and threatened breach in patients who were ambulatory

and fully effective just before bismuth treatment was begun. Larger doses of bismuth are quite capable of producing the shocks and paradoxes of the larger doses of the arsphenamines, eventuating at times and quite unexpectedly in sudden death. For that reason, mercury in the form of the inunction or the succinimide given two or three times weekly by intramuscular injection still holds a legitimate and conservative place in the treatment of syphilitic cardiovascular disease. The earlier the aortitis; the higher in the vessel the involvement occurs; the more complete the absence of coronary symptoms; and the less the evidence of cardiac embarrassment, the stronger, more intense and more rapid can be the therapeutic approach. In fact the tolerance of uncomplicated syphilitic aortitis for the arsphenamines, when the disease is in its earliest stages, is such that the observations both of Moore, Danglade and Reisinger,<sup>1</sup> and of the Cooperative Clinical Group,<sup>15</sup> seem to justify the use of 0.45 Gm. neoarsphenamine as a maximum dose to be reached by the third or fourth injection of an ordinary 8- or even 10-injection series. It is to be stressed, however, that the administration of neoarsphenamine in cardiovascular syphilis must be so conducted that no reactions to the treatment are produced. Arsphenamine proper (606) should, in general, *not* be employed.

Should treatment be begun with an arsphenamine? It is notable that the Cooperative Clinical Group's recommendations still adhere to the conception of an introductory course or courses of heavy metal as a preparation. This, in our opinion, is particularly essential when aortitis has progressed to the appearance of a diastolic murmur; when an aneurysmal grade of aortic dilatation, and especially a small localized sac, is demonstrable by x-ray; when a differentiation between a tumor and a large aneurysm is to be made; when a large aneurysm is known to exist; when myocardial disease, as shown by the electrocardiogram, or coronary disease, as shown either by this means or by symptomatology, is present.

The selection of a form of preparatory treatment is not a matter of rule, but of individual case decision. Even in early uncomplicated aortitis and always in the presence of definite leakage the patient should, for a period of two months or more after treatment begins, reduce his activities or even submit

to rest in bed while the therapeutic shock adjustment takes place and healing and compensation for the defect are established. Getting in a hurry on the part of the doctor, and over-activity on the part of the patient, take especially heavy toll of what might otherwise be good results in this initial period. The prevention of shock and paradox of injurious grade is accomplished by an interplay between the activity of the drug, the amount of it administered per treatment, the interval between treatments, the resting of the patient, and the supporting of the circulatory machinery by such agents as digitalis. The gravity of the first breach in compensation for a patient with cardiovascular syphilis is, as we have said, now clearly recognized, and it is much wiser to be a bit exacting on the preventive side and slow on the therapeusis than to tax the patient to the point of even a mild decompensation. Within the skeleton of principles outlined, it is then possible to develop a satisfactory technic of dealing with the majority of cases. whether the mercurial inunction, minute doses of water-soluble bismuth (sodium bismuth tartrate), very small ascending doses of neoarsphenamine (25 mg. increment added to this as an initial dose), or bismuth arsphenamine sulfonate (bismarsen) in the same dosage is used. The courses are longer than in the more standard treatment of an uncomplicated early aortic case, the intervals between even the smallest doses of any of the last mentioned drugs seldom less than three or four days. *No attention should be paid to the failure to reverse blood serologic tests.* If and when possible, information should be obtained as to the spinal fluid and central nervous system findings. Reversing the dictum, more attention paid to the state of the cardiovascular mechanism, especially in patients in their late fifties and sixties, before any form of treatment for a neurosyphilis is undertaken, would forestall some serious and even fatal therapeutic decisions, especially in the use of fever therapy. While cardiovascular syphilis stands treatment better than, in the reaction again early paradoxical fatalities, we came to believe it would; and while it is now proved that neoarsphenamine materially betters results, caution and conservatism are still very much in order.

Even after years of observation, the action and use of iodide in cardiovascular syphilis are still a perplexity. Its slow effects

have been lost sight of too, in the spectacular action, for better or worse, of more modern drugs. Personally we have seen neither advantage from nor excuse for preference of one over another iodide, or the use of very large doses. Potassium iodide in 5- to 10-grain doses three times daily, two months on and two off, has been our most serviceable formula, continued in late cases over periods of years.

Is it possible statistically to maintain the worth of modern treatment in syphilitic aortic disease? With adequate treatment set, as before, at 20 properly graded arsphenamine or neoarsphenamine injections, and the appropriate heavy metal therapy, the Cooperative Clinical Group<sup>15</sup> material showed that the outlook of patients with uncomplicated syphilitic aortitis, followed for one year, had been improved, and the life span of those who died had been lengthened from an average of thirty-four to eighty-five months. Small arsenical dosage prolonged life twenty months more than the larger ones. Of patients adequately treated after the detection of their aortitis, 63 per cent were found to be living, symptom-free and arrested; while of those inadequately treated only 49 per cent were so found.

Perhaps a final word might be offered in explanation of a finding after treatment which sometimes does the doctor's cardiovascular mechanism more injury than it does the patient's. This is the so-called "paradoxical increase in signs" which may occur even with the bringing of the aortic syphilitic process to a standstill and the general functional improvement of the patient. This paradoxical effect manifests itself, for example, in the patient who has been recognized as having a syphilitic aortitis with a systolic aortic murmur, but no regurgitant diastolic murmur. Six months after adequate and carefully graded treatment for the aortitis has been administered, he is found to have not only his aortic systolic, but also a diastolic murmur, and perhaps some definite evidence of cardiac enlargement incident on the regurgitation. Is this patient worse or better as the result of the treatment he has received? Enough of these instances have now accumulated so that we believe it is safe to say from observation of them that they have simply exchanged a static disability for a progressive and threatening one. If they had not been treated they would ultimately have

gone on to a far more advanced grade of aortic damage than that made manifest in their healing sclerosis. The paradoxical effect is observable in a wide range of syphilitic aortic disease, and may take the form of the development of outright aneurysm upon a merely pulsating and somewhat widened aorta; the enlargement of an aneurysm beyond the size observed at the time treatment was begun; the development of aortic systolic as well as aortic regurgitant murmurs; the appearance of transient signs of decompensation in many patients with what appear to be very mild grades of aortic involvement due probably to temporary disturbance of the coronary circulation; and finally to the recognition in subsequent fluoroscopy of aortic dilatation and pulsation which, as in one of our most recent cases, surprised the cardiologist, who had expected an entirely different effect from properly conducted treatment.

We have presented this subject more in the form of an oration than a clinical demonstration because it has seemed to us that above all else statements of principle, even though some of them have only tentative quality and coloring, are more needed in this field than is a mere multiplication of case instances. Syphilitic cardiovascular disease has been far too well considered by the case, and far too little in the aggregate and by principle. As the weak spots in the frame of principles are more carefully studied (*vide* the differential field between syphilitic and other forms of aortitis), the general practitioner can expect a widening of his usefulness in the special treatment of late cardiovascular syphilis. In the field of prevention, however, he stands today as the holder of the strategic position. Once he has mastered the principles of effective treatment of early syphilis, the rôle of the cardiovascular specialist with respect to this particular disease will fade into obscurity.

## CLINIC OF DR. JOSEPH B. VANDER VEER

### PENNSYLVANIA HOSPITAL

---

#### THE DIAGNOSIS AND TREATMENT OF ABNORMAL CARDIAC RATES AND RHYTHMS

DISTURBANCES in the rate and rhythm of the heart are frequent. Occurring in persons with normal hearts they may produce symptoms sufficient to cause alarm. With organic heart disease existing symptoms may be aggravated and the prognosis unfavorably altered. In other cases the onset of an arrhythmia is a sign of activity of myocardial disease or a warning signal denoting overtreatment. As in the whole of medicine, correct diagnosis is the foundation of good treatment.

The more widespread use of the electrocardiogram has led to a new interest and accuracy in the diagnosis of these conditions. Sir James Mackenzie said, "The eventual use of machines in diagnosis is to teach us how to do without them." It is rare that a patient with an arrhythmia or tachycardia cannot be correctly diagnosed and treated by clinical methods alone, if the physiology and clinical signs of these conditions are known to the observer. In this discussion emphasis will be placed on the clinical examination. A few electrocardiograms are included with the hope that even those unfamiliar with this method of examination may be given a mental picture of the physiologic changes which occur in these disturbances.

#### SINUS ARRHYTHMIA

This is one of the most common disturbances of cardiac rhythm and usually results from the vagus effect on the sino-auricular node, or pacemaker. It is most frequent in children and young adults. Its main importance lies in its differentiation from other arrhythmias. It is usually associated with

respiration and the condition can be accentuated (thus aiding in diagnosis) by having the patient breathe deeply and slowly. Once regarded with some importance it is now thought to be of little clinical significance and no treatment is indicated.

### PREMATURE BEATS

Premature beats, or extrasystoles as they are often called, are frequently seen in both normal and diseased hearts. Patients often consult a physician because of the symptoms produced. In other instances, often more important, frequent premature beats are present without the patient being aware of the arrhythmia. These ectopic contractions may arise from any portion of the heart muscle or conduction tissue. Occasionally the premature contraction is "interpolated" between two normal beats, a true "extrasystole." As a rule, however, the premature beat replaces the next ventricular contraction, the ventricular muscle being in the refractory stage when the regular stimulus reaches it. The pacemaker in the auricle continues the rhythm and the ventricles respond to the succeeding stimulus. This compensatory pause is characteristic of premature beats, though it may not be of complete length in the auricular type where the pacemaker is disturbed.

**Diagnosis.**—The diagnosis of premature beats is often suspected from the history, the patient complaining of a "flopping" or "turning over" sensation in the cardiac area. They are more apt to occur when the heart rate is slow, as after retiring or on arising in the morning. On auscultation of the heart the regular rhythm is broken by an audible premature beat, followed by a compensatory pause. The sounds of the premature contraction often vary slightly from the normal. Only one sound (the first) may be heard when the contraction is too weak to open the aortic valves, or there may be a "tumbling" quality to the cycle with three quick, distinct sounds. Coincident palpation of the pulse reveals no wave or one of diminished volume followed by a pause. Premature beats arising in the auricle or A. V. nodal tissues may produce a pulse wave as the stimulus reaching the ventricles follows the usual conduction path and the resultant contraction is a competent one. One of the most valuable signs of digitalis intoxication in a patient with normal rhythm is the appearance

of premature beats. If the drug is continued a coupling of premature beats may occur (*i. e.*, each normal contraction is followed by a premature one). A slow, regular pulse may be present—the premature contractions producing no pulse wave, and the condition inaccurately diagnosed as heart block. A coupling of the pulse is sometimes present, however, especially if the premature beats arise in the auricle. In these cases the second pulse wave is distinctly smaller than the first. Differentiation of this condition from the more rare true pulsus

Fig. 55.—Electrocardiograms showing the difference between premature beats and partial heart block. *A*, Lead I, from a case with ventricular premature beats. Note the aberrant ventricular complexes produced by the premature beats (X) and the compensatory pause. *B*, Lead II, from a case of delayed auriculoventricular conduction with occasional failure of the stimulus to reach the ventricle. Note the prolonged P-R interval and the failure of ventricular contraction (X). These two conditions may give identical "dropped beats" in the pulse but coincident auscultation of the heart reveals the true diagnosis.

alternans is easily done clinically, for in the latter the pulse waves are equally spaced. Coupling with premature beats is most apt to occur in patients with severe myocardial damage. It should be stressed that in this type of patient (who often has the greatest need for the drug) the margin of safety between the therapeutic and toxic dose of digitalis is least. The appearance of this rhythm in a patient receiving digitalis is a signal for immediate cessation of the drug.

Frequent premature contractions from many foci, occurring

with an increased heart rate, may be most difficult to distinguish from auricular fibrillation. In both, irregularity in force and rhythm of the pulse with pulse deficit may be present. Frequent, careful examination of the patient will suffice to differentiate the two in most cases, though occasionally an electrocardiogram is essential.

Irregularity of the pulse from partial heart block may exactly resemble that seen with premature beats. If the heart sounds are well heard, however, the two conditions are easily classified, the premature beats being audible whereas the failure of the ventricle to contract in heart block leaves those intervals of the cardiac cycle without sound (Fig. 55).

**Treatment.**—In those patients in which no evidence of organic heart disease is found reassurance that the condition is not serious should be given. The etiologic factor may be a minor one and easily removed if located. The combination of fatigue, worry, and increased use of tobacco is a common cause. Foci of infection, especially apical abscesses of the teeth, are responsible for some cases. Improvement of the general health when secondary anemia and chronic infections are at fault, may prove beneficial. The time-honored use of strychnine and quinine is probably based on an increase in the cardiac rate and a decrease in cardiac irritability, though removal of the cause whenever possible is more desirable. In those patients with irritable hearts having frequent premature beats and periods of tachycardia the use of quinidine may be indicated (see paroxysmal tachycardia).

Infectious diseases, especially pneumonia, often show premature beats at some time during their course. Myocardial involvement by a toxic or infectious process is suggested but no special therapy is indicated in most cases.

In patients with organic heart disease the presence of frequent premature contractions, especially if the heart rate is elevated, suggests an active myocardial affection. Frequent auricular premature beats may be a forerunner of auricular fibrillation. When extrasystoles appear after coronary occlusion (acute myocardial infarction) it may be a warning that ventricular fibrillation is imminent. The use of quinidine sulfate, 3 grains every four hours, when awake, is rational

therapy to reduce the irritability of the ventricular musculature and lessen the possibility of this fatal rhythm.

The appearance of premature beats during digitalization or in patients on a maintenance dose of digitalis is a sign to proceed cautiously. If they become frequent or a coupled rhythm is noted the drug should be stopped *at once*, even though nausea and vomiting or other symptoms of intoxication are absent. Premature beats, *per se*, however, are not a contraindication for digitalis. Occurring in a patient with heart disease who has received none of the drug, digitalis should be given if there are signs of myocardial insufficiency. In these cases the irregularity may lessen or disappear with digitalization. The same may be said of nausea and vomiting in patients who have received but small doses of digitalis. If these symptoms are due to passive congestion of the liver and stomach the indication is for more, rather than less digitalis.

#### PAROXYSMAL TACHYCARDIA

Paroxysmal tachycardia is characterized by the abrupt onset of a rapid, regular heart action persisting for a period of a few seconds to a few days and terminating abruptly. The condition has been likened to a rapid succession of premature beats and similarly, the focus of irritability may be located in the auricle, A. V. nodal tissues or the ventricle. It occurs frequently in hearts with no evidence of disease and in these cases is seldom serious. When an attack persists for several hours in a patient with organic heart disease signs of decompensation may appear. The type of paroxysmal tachycardia usually seen originates in the auricle or A. V. nodal tissues and has a rate of 160 to 220 per minute. Even more rapid rates are occasionally seen. The more serious, but uncommon, ventricular tachycardia is seen after myocardial infarction and with overdosage of digitalis. The rate is usually less rapid and often a slight irregularity in the rhythm is present. Ventricular fibrillation is to be feared in these cases.

**Diagnosis.**—The diagnosis of paroxysmal tachycardia is often suspected from the history. The abruptness of onset and termination are characteristic and previous similar attacks have usually been experienced (Fig. 56). Palpitation is nearly always present. Shortness of breath, weakness, and dizziness

are common. Auscultation of the heart reveals a rapid regular rhythm. No pulse deficit is present and the volume of the pulse is constant, though small. Accurate determination of

Fig. 56—Electrocardiogram of a complete attack of paroxysmal tachycardia (continuous record of Lead II). Normal sinus rhythm is present at the first of the record with an isolated premature beat shown at 1. The abrupt onset of the tachycardia is evident at 2. The rate is 172 per minute and the attack lasts 9.2 seconds. The abrupt cessation of the attack occurs at 3. Normal rhythm is resumed at 4 with a rate of 78 per minute. The focus of origin of the premature beat and tachycardia is in the auriculo-ventricular bundle (His). The "paroxysmal" character of the condition is well shown.

the pulse rate may be difficult but the correct rate of the tachycardia can usually be determined by the stethoscope. This condition must be differentiated from *auricular flutter* and

rapid *auricular fibrillation*. Though these latter rhythms may occasionally be paroxysmal in type they are usually persistent and more apt to occur with organic heart disease. The ventricular rate in flutter is usually at or below 160 per minute whereas that of tachycardia is commonly above this rate. Very rapid pulse waves may be seen in the neck veins (due to auricular contractions) in some cases of auricular flutter. Pressure over the carotid sinus area may produce slowing of the arterial pulse (during the time of pressure) in flutter. Very rapid auricular fibrillation may give the impression of a regular heart rate to auscultation, especially if one does not listen specifically for slight arrhythmia. Coincident palpation of the pulse, however, reveals irregularity in force and rhythm with a marked pulse deficit. This clinical observation differentiates fibrillation from tachycardia.

Ventricular tachycardia should be suspected when a patient with severe heart disease who is receiving digitalis develops a rapid heart rate. It is also apt to occur following coronary thrombosis. The final differentiation from auricular and nodal tachycardia must be made by the electrocardiogram.

**Treatment.**—Patients with frequent attacks of paroxysmal tachycardia often discover various methods of terminating the attacks. Holding the breath, taking a deep inspiration and “bearing down,” a drink of ice water, the induction of vomiting by an emetic or putting the finger down the throat, pressure on the neck or eyeballs and other procedures may prove efficacious in the individual case. Probably the most frequently successful method of terminating an attack is by pressure on the right carotid sinus. The patient should be flat or semi-recumbent so the neck is relaxed. The first three fingers are rolled medially over the sternocleidomastoid muscle and the carotid artery palpated just below the angle of the jaw. Firm continuous pressure is made so as to compress the artery against the underlying structures. This is continued for ten to twenty seconds and it may be necessary to exert considerable pressure. If unsuccessful, the measure should be repeated in slightly different areas.

When the tachycardia persists the patient should be kept quiet and in a comfortable position, usually recumbent. An ice-bag should be placed on the precordium and a sedative

given. If much discomfort is present morphine hypodermically is indicated. The attacks usually terminate in a few hours and the patient quickly returns to his usual health. If organic heart disease is present symptoms of cardiac failure may soon appear and more drastic measures are indicated. Quinidine sulfate, 3 to 6 grains, should be given every two to three hours for several doses. The use of acetyl-beta-methylcholine chloride (mecholyl) may prove successful when other measures fail. This drug, a powerful parasympathetic stimulator, is given hypodermically in doses of 15 to 30 mgm. Flushing of the skin, increased peristalsis and even bronchial spasm quickly occur and the tachycardia may terminate within two or three minutes. Pressure on the neck may again be tried if the drug does not act favorably alone. Because of possible severe reactions a hypodermic of atropine sulfate,  $\frac{1}{75}$  grain, should be immediately available and given at once if untoward symptoms are noted.

If ventricular tachycardia is suspected in patients receiving digitalis the drug should be stopped at once and quinidine started. Occurring after coronary occlusion it is an ominous sign but treatment may be successful and quinidine is probably the drug of choice. Rarely, short attacks of paroxysmal tachycardia recur with such frequency as to be disabling. In these patients improvement of the general health and removal of foci of infection are important. Quinidine sulfate may prove of value in reducing the number of attacks and should be tried in doses of 3 to 6 grains, three or four times daily. The drug can be continued for long periods of time though occasionally diarrhea or a troublesome dermatitis may occur and limit its use.

#### AURICULAR FLUTTER

This important but uncommon condition is usually associated with heart disease and may persist for weeks or months if untreated. It is most often seen with arteriosclerotic heart disease but occurs with rheumatic heart disease and occasionally with thyrotoxicosis. The process in the auricles is characterized by a regular circus movement stimulating the auricles to rapid contraction, usually at a rate of 260 to 320 per minute. A 2:1 auriculoventricular heart block is commonly present so the ventricular rate observed is from 130 to 160 per

minute. The patient is frequently unaware of the increased heart rate and may be brought to the physician by the symptoms of cardiac insufficiency.

**Diagnosis.**—Auricular flutter should be thought of in any patient with a heart rate of 120 to 160 per minute, which persists for several days or weeks with little variation in rate. If the condition is considered the diagnosis can usually be proved clinically. Careful inspection of the neck veins may reveal rapid venous pulse waves, caused by the auricular activity. This observation may be facilitated by having the patient in the prone position so as to distend the veins. Pressure on the carotid sinus area, as described under paroxysmal tachycardia, will often produce slowing of the ventricle rate in auricular flutter. The original rapid rate is quickly resumed on release of the pressure. This test may be of value in differentiating flutter from paroxysmal tachycardia. In the latter case there is no slowing of the heart rate—the attack being either abruptly terminated or no change in rate occurs. Occasionally, when a 3:1 or 4:1 auriculoventricular heart block is present in auricular flutter the slow, regular ventricular rate will be regarded as normal sinus rhythm. With a mixed auriculoventricular block and a rapid, irregular ventricular rate, auricular flutter is nearly identical with auricular fibrillation clinically and usually will be regarded as such. As the treatment is identical this error is of no practical importance. The treatment of auricular flutter will be discussed with that of auricular fibrillation.

#### AURICULAR FIBRILLATION

This condition is the most frequent, persistent arrhythmia and easily the most important of the disturbances of cardiac rhythm. It is closely related to auricular flutter. The circus movement in auricular fibrillation is more rapid, however, being in the neighborhood of 500 per minute, and follows an irregular course. Coordinated contractions of the auricles do not occur as in flutter or normal rhythm and they have aptly been described as being in a state of "tremulous diastole." This inactivity of the auricles impairs ventricular filling and favors thrombus formation in the appendages. The ventricles are bombarded by the numerous small stimuli from the muscle fiber contractions of the auricles. The bundle of His, because

of its refractory period, conducts only a portion of these stimuli. The resultant ventricular response is usually a rapid rate with a very irregular rhythm. When some degree of heart block is present from disease or as occurs with digitalis therapy, the ventricular rate will be slower, at times even below that usually seen with normal sinus rhythm. The auricular phenomena in these cases, however, remain unchanged.

Rarely, auricular fibrillation occurs in short paroxysmal attacks in individuals with no demonstrable heart disease. These attacks are apt to follow indiscretions in food and drink, severe fatigue, or overexertion. Persisting from a few minutes to a few hours, they usually subside spontaneously. During the course of severe infections, especially pneumonia, in toxic states from various causes, and occasionally postoperatively this rhythm may occur and persist from a few hours to a few days.

The development of auricular fibrillation in a patient with organic heart disease may at once change the prognosis and treatment. If the ventricular rate is rapid cardiac decompensation is to be expected, the rapidity of development depending on the myocardial reserve. Embolism is not infrequent in established auricular fibrillation, being more common in those patients with mitral stenosis, which augments the auricular stasis already present and favors auricular thrombus formation.

Etiologically, most cases of auricular fibrillation are associated with rheumatic heart disease or arteriosclerotic heart disease. Thyrotoxicosis is a much less frequent, but important cause. Most cases below forty years of age are in patients with mitral stenosis. In the older patients coronary sclerosis with or without hypertension is the usual cause. Hypertensive heart disease in adults of the younger age groups is seldom associated with the condition and it is practically never seen in syphilitic heart disease.

**Diagnosis.**—Characteristically, auricular fibrillation has a rapid, totally irregular ventricular rhythm with a pulse deficit. The pulse is irregular in force and rhythm. Any patient with a heart rate continuously above 120 per minute and totally irregular in rhythm can be safely regarded as fibrillating. As the heart rate increases the pulse rate becomes relatively less, due to the greater pulse deficit. With very rapid rates the

heart may sound nearly regular to auscultation but coincident palpation of the pulse shows that many of the contractions do not produce a pulse at the wrist. This dropping of pulse beats (pulse deficit) differentiates the condition from *paroxysmal tachycardia*. Taking the blood pressure may also aid in the diagnosis of auricular fibrillation. No regular upper level of systolic pressure is found, but rather a medley of beats is heard at different systolic levels. If the ventricular rate is inherently slow (partial heart block being present) or controlled by digitalis therapy, the rhythm may be remarkably regular. With a rate of about 70 per minute, or less, it is easily mistaken for *sinus arrhythmia*, occasional *premature beats* or even *normal sinus rhythm*. The error is not of great importance if the rate is fundamentally slow as no specific treatment is usually necessary. However, the mistake of stopping digitalis in well regulated cases because the "rhythm seems nearly regular" should be carefully avoided. Due to the prolonged effect of digitalis the ventricular rate shows little change for two or three weeks and the patient and physician are given a sense of false security. After this period the rate will rise rapidly to the original level and the improvement in cardiac reserve which has been gradually won may be quickly lost.

**Treatment.**—Congestive heart failure is often present in patients with auricular fibrillation or auricular flutter. Complete bed rest, light diet, free movement of the bowels, limitation of fluid intake to 1200 or 1500 cc., and the securing of sleep by morphine hypodermically, are all important measures in these cases.

Digitalis is the important drug in the treatment of these two conditions. It is indicated in practically all cases in which the ventricular rate is more rapid than normal, whether or not heart failure is present. The fundamentals of digitalis therapy can be stated as follows:

1. The *preparation of choice* in nearly all cases is powdered digitalis leaves in capsule or pill form.
- 2 The *digitalizing dose* is *sufficient* of the drug to produce beneficial effects with a minimum of toxic symptoms.
- 3 The *maintenance dose* of digitalis is that amount which gives the maximum cardiac efficiency; usually given daily, and often continued for life.

At the present time there is practically unanimity of opinion among cardiologists that the most efficient form of the drug is the whole digitalis leaf. It is more stable than the tincture and the dose prescribed is less apt to be altered by the druggist or patient. There are many excellent preparations of the glucosides of digitalis available at the present time. There is no proof, however, that these products have *any* advantage over a well standardized preparation of digitalis leaves, and the cost to the patient is usually greater. The psychic effect of a different appearing tablet may occasionally be a factor to be considered in patients who have been nauseated by digitalis or those convinced they are "sensitive" to the drug.

The amount of digitalis necessary for digitalization varies greatly in different patients. I am not convinced there is any advantage in prescribing digitalis according to the weight of the patient. While this may be a safe dose in most cases, it is not invariably so, and the best interests of the patient will be served if the drug is given in divided doses, three or four times daily, continuing this until improvement or toxic effects are manifest. Close observation is important, for in a patient with a badly damaged heart *signs* of toxicity may appear before symptoms, and either or both may occur before beneficial effects. In a moderately ill patient with rapid auricular fibrillation an initial dose of 6 to 9 grains should be given. The drug is then started in doses of  $1\frac{1}{2}$  grains (1 cat unit) three or four times daily. Careful observation should be made of the patient at least once daily, particularly noting the *heart rate*. As the ventricular rate slows the pulse deficit lessens and the quality of the pulse improves. The drug is given until the *heart rate* is in the neighborhood of 80 per minute. The dose is then reduced to once or twice daily. Usually four or five days are required to slow the ventricular rate, but more or less time may be needed, depending on the individual. In an ambulatory patient, a  $1\frac{1}{2}$ -grain tablet may be safely given three times daily (after meals) for one week. In a very ill patient with a rapid ventricular rate and congestive heart failure the indication is for digitalis intravenously. In these emergencies quick action of the drug may be life-saving. A purified tincture should be used in doses of 4 cat units and repeated in four hours. The drug can also be started by mouth.

Intramuscular or subcutaneous injection of these preparations is *not* to be recommended. One would hardly expect a drug

FIG 57—Electrocardiograms from a patient with auricular flutter, showing the effects of digitalis therapy (all Lead II) A, Record obtained during a short paroxysm of 1:1 flutter (no heart block). Auricular and ventricular rate 270 per minute. B, 2:1 heart block. Auricular rate 272. Ventricular rate 136 (before treatment). C, Record after 30 grains of digitalis leaves. Auricular flutter with 2:1, 3:1 and 4:1 heart block. D, After 36 grains digitalis leaves. Auricular fibrillation. Ventricular rate about 70. Note the change in the waves caused by auricular activity. Digitalis stopped. E, Return to normal sinus rhythm. Auricular and ventricular rates 82 per minute.

which is irritating and poorly absorbed to be efficacious when the circulation is failing.

In *auricular flutter* digitalis is also the drug of choice. Large doses are often needed and close observation of the patient is essential. The drug is given in divided doses totalling 6 to 9 grains daily and continued until slowing of the ventricle occurs. Reversion to auricular fibrillation is the rule and if the drug is then stopped many of the patients will return to normal rhythm (Fig. 57). In some patients auricular fibrillation continues after the flutter has been eliminated by the digitalis therapy. In these instances digitalis should be continued in sufficient dosage to control the ventricular rate, fibrillation being a much more satisfactory rhythm to control than flutter.

The maintenance dose of digitalis varies considerably and again shows little relation to the weight of the patient. It is best determined by clinical trial. The most frequent satisfactory dose is  $1\frac{1}{2}$  grains of the powdered leaves daily. The important thing in auricular fibrillation is to give sufficient of the drug to keep the heart at 70 to 80 per minute. This may take from  $\frac{3}{4}$  grain to 3 grains daily. Counting the heart rate by auscultation is always necessary, the pulse rate being unreliable if the heart rate is much above normal.

If difficulty is found in controlling the heart rate in auricular fibrillation several things should be considered. The most frequent cause is insufficient digitalis, and this factor should be carefully checked from all angles. An unrecognized hyperthyroidism may keep the heart rate above normal. Frank exophthalmic goiter will seldom be overlooked but a mild degree of thyrotoxicosis may be superimposed on existing heart disease and be the cause of marked disability. Proper treatment of the thyroid condition may restore the patient to fairly good health, whereas if the thyrotoxicosis remains unrecognized, cardiac compensation may be impossible.

Toxic effects of digitalis, affecting the rhythm, are more difficult to detect clinically when auricular fibrillation is present. Rarely, the ventricular rate may *increase* with treatment as the result of many ventricular premature beats. It is hardly possible to detect this condition clinically though it is easily determined by the electrocardiogram. More often, premature beats appearing as the result of treatment occur when the heart rate is relatively slow and can be suspected

clinically by the closeness of the beat and the coincident pulse deficit. It should be noted that auricular fibrillation may occasionally be a *manifestation* of digitalis toxicity. Occurring during the treatment of a patient with normal rhythm the heart rate is usually slower with the onset of auricular fibrillation and even complete heart block may coexist with this rhythm. On removal of the digitalis normal sinus rhythm will usually be resumed.

Fig. 58.—Electrocardiograms to illustrate the treatment of auricular fibrillation by quinidine therapy (all Lead II). *A*, Before any therapy was begun. Ventricular rate about 165 per minute. *B*, After 27 grains of digitalis leaves. Auricular fibrillation still present. Ventricular rate about 75 per minute. *C*, After 33 grains of quinidine sulfate (over a forty-eight-hour period). Return to normal sinus rhythm. Auricular and ventricular rates 76 per minute.

Quinidine sulfate is a valuable drug in the treatment of certain patients with auricular fibrillation. Its action is nearly the antithesis of that of digitalis. It decreases cardiac irritability and tone. When successful in the treatment of these cases the circus movement in the auricles is interrupted with a return to normal sinus rhythm. The immediate and ultimate success depends on the proper selection of cases, only a small number of the total being suitable. The ideal cases for this form of therapy are those in which auricular fibrillation is the only evidence of heart disease. Patients with only slight evi-

dences of heart disease and auricular fibrillation of short duration will usually have satisfactory results. Thyrotoxicosis cases in which normal rhythm does not obtain after elimination of the toxic factor are good cases for this therapy. *Contraindications* to this drug are long-standing auricular fibrillation (over six months), marked cardiac enlargement and the presence of signs of heart failure. In using quinidine sulfate to terminate auricular fibrillation it is wise to digitalize the patient first to control the ventricular rate (Fig. 58). The digitalis is then stopped and one dose of quinidine (3 grains) given to test for sensitivity. If no untoward reaction occurs it is begun in doses of 3 grains every four hours, when awake. The second day it may be given every three hours, and the third day 6 grains every four hours. This dosage may be continued for a total of one week. Larger doses are advocated by some and may occasionally be successful when smaller amounts of the drug fail. After return to normal rhythm the dosage of quinidine may be gradually "tapered off" over a period of a few days. Occasionally it may be wise to continue quinidine in doses of 10 to 15 grains daily over a long period of time. Rarely, digitalis and quinidine may be given simultaneously. An indication for both drugs might be as follows: a patient with organic heart disease in which digitalis was indicated, having also frequent attacks of paroxysmal tachycardia. Such attacks might be lessened in frequency and duration by the judicious use of quinidine in divided doses. Exceptions to the contraindications given may occur but in general it is wise to adhere rather closely to these. Fatalities occurring after quinidine therapy are exceedingly uncommon when the cases are properly chosen.

In summary, it is hoped sufficient emphasis has been placed on the clinical differentiation of the important disturbances in cardiac rate and rhythm. Space has not permitted a complete discussion of the subject, some of the less important arrhythmias as sino-auricular block and A. V. nodal rhythm being omitted. Heart block is considered only in differential diagnosis. Finally, it should be stated that the court of appeal in difficult cases is the electrocardiogram. Familiarity with and more frequent use of this method of examination will improve one's clinical diagnostic ability.

## CLINIC OF DR. EDWARD WEISS

TEMPLE UNIVERSITY

### SYMPTOMS OF HEART FAILURE IN HYPERTENSION

RECENT studies by the Metropolitan Life Insurance Company show that every other individual past the age of fifty in the United States dies of cardiovascular-renal disease. More than one half of this number are cardiac deaths and the greatest single cause is hypertensive-vascular disease. This indicates the importance of the topic assigned, that is, the symptoms of heart failure in hypertension. But essential hypertension is not the only variety of hypertension that produces heart symptoms. Heart complications also occur in glomerulonephritis, both the acute and chronic varieties, sometimes during the course of the toxemia of pregnancy and also in congenital stenosis of the isthmus of the aorta. These latter causes, however, are probably responsible for only about 5 per cent of the instances of heart disease due to hypertension. All the rest are due to the condition that is usually termed "essential hypertension." It is hardly necessary to spend much time discussing what is meant by that.

The generally accepted concept of essential hypertension is a vasospastic disorder, widespread in the civilized world, that manifests itself chiefly in middle life, usually runs a course of about ten to twenty years after its discovery, leads gradually to thickening and constriction of the smaller vessels so that life eventually is terminated by failure of one or another of the vital organs—heart, brain or kidneys.

### PATHOGENESIS OF HEART FAILURE IN HYPERTENSION

This brief statement must suffice to introduce us to the important relationship that exists between essential hypertension and heart disease. It leads the list of the causes of heart

failure. How then is this heart failure brought about? The explanation is not clear in all cases but in the majority after essential hypertension has persisted for a period of years hypertrophy of the left ventricle of the heart occurs. So well is this fact recognized that when we meet with hypertrophy of the heart that is not due to a valvular defect it can almost always be explained on the basis of essential hypertension. But the question arises why does the hypertrophied heart fail? And again the answer to this question is almost as obvious as the cause of the hypertrophy—failure occurs because of coronary artery sclerosis which interferes with the nutrition of the heart muscle. This introduces us to a more difficult question; that is, the relationship between coronary artery sclerosis and essential hypertension. Coronary artery sclerosis occurs as a part of a more widespread atherosclerosis which affects principally the aorta and its branches—a senile, degenerative process of the large vessels not necessarily related to essential hypertension. The day has fortunately passed when we considered that arteriosclerosis was responsible for essential hypertension. Now we know that essential hypertension is a vasospastic process which precedes arteriosclerosis rather than follows it. We also know that this latter form of arteriosclerosis is a diffuse hyperplastic sclerosis affecting small vessels, an *arteriolosclerosis*, in contrast to the above-mentioned senile, degenerative process which affects larger vessels. I prefer the term “hypertensive-vascular disease” for the one form and atherosclerosis, which may occur entirely independently and is certainly of another origin, for the other. Nevertheless, the two processes are frequently associated, that is, they coexist, mainly because essential hypertension is the most frequent disorder of middle life and atherosclerosis is the most frequent disorder of later life and individuals with essential hypertension live into the age period when they develop atherosclerosis. It is probably also true that when these processes coexist their development is accelerated. Hence it is that essential hypertension is frequently complicated by coronary artery sclerosis. Under such circumstances the individual is in greater danger than if either process existed alone because the heart is forced to work harder as a result of the essential hypertension and at the same time a slow but certain interference with the nutri-

tion of the heart is occurring. So we may say that the ability of the heart to carry on in the presence of essential hypertension depends largely upon the integrity of its blood supply through the coronary vessels. These statements we may accept for our clinical purposes although it is quite true that there are instances of failure of the heart in the course of essential hypertension that cannot be explained on the basis of coronary artery disease.

The question with which we are immediately concerned is—how does this failure of the heart in the course of hypertension manifest itself?

#### ONSET OF HEART FAILURE

Evidences of heart failure may be insidious or sudden in onset. For a long time, in the majority of instances, there are no symptoms. During this period hypertrophy of the left ventricle is taking place but since the heart is entirely capable of meeting all demands made upon it no symptoms occur. The first and most important symptom that occurs is shortness of breath on exertion and it may precede by months or years any further evidence of heart disease. However, other symptoms may occur concomitantly or follow in quick succession after shortness of breath occurs. Palpitation is a frequent symptom and may occur with or without a disturbance in the rhythm of the heart. One of the most frequent and important disturbances in rhythm in the hypertensive form of heart disease is auricular fibrillation. It is a serious complication, the anatomic basis of which is atherosclerosis, an associated mitral stenosis or thyroid disease. It may also occur in association with coronary thrombosis and occasionally as a functional disturbance. In the latter instance it is not so serious as when due to the previous causes mentioned. Other disturbances in rhythm are paroxysms of tachycardia and premature beats. When heart failure has advanced to a serious degree gallop rhythm may make its appearance and must be carefully sought for because of its prognostic value.

As heart failure continues, dyspnea becomes more pronounced, cough and expectoration follow, and finally orthopnea is established. As complete failure sets in, and frequently in association with gallop rhythm, early Cheyne-Stokes breathing

makes its appearance. This disturbance in respiratory rhythm can often be observed best at night or at times when the patient dozes off. Dyspnea of heart failure may be associated with or exaggerated by other causes of dyspnea such as obesity, pulmonary emphysema, kidney disease, anemia or psychic factors. Its relationship to the dyspnea of emphysema is an important consideration frequently neglected. It often happens that an individual with dyspnea which is thought to be of cardiac origin has a perfectly normal heart but suffers from pulmonary emphysema. Frequently such patients are told that they have heart disease and dosed with digitalis when in reality the dyspnea is bronchial in origin and the heart is normal or nearly so. In regard to the latter question it also frequently happens that both heart disease and pulmonary emphysema are present so that the dyspnea is of combined origin. If possible we must attempt to evaluate this dyspnea by saying how much is due to the cardiac disease and how much is due to the coexisting pulmonary emphysema. Dr. Morris Kleinbart and I have worked on this problem by circulatory measurements—velocity time and venous pressure estimations—in addition to special fluoroscopic studies made by Dr. Hugo Roesler. We believe that we have been helped by these special observations in determining in many instances of combined chronic heart and lung disease which was the more important factor in the production of dyspnea.

#### CARDIAC ASTHMA: LEFT HEART FAILURE

This differentiation of heart and lung causes for shortness of breath becomes even more important under another set of circumstances. This brings us to the consideration of a form of dyspnea that occurs in heart disease that is just as important as the dyspnea of exertion and that is dyspnea that occurs chiefly at night as a paroxysm and is usually referred to as an attack of cardiac asthma. Usually the clinical differentiation from bronchial asthma is not difficult but under some circumstances, especially in the elderly, it may be impossible to say whether this paroxysmal attack is cardiac asthma or true bronchial asthma. It is an important problem because the prognosis and treatment differ so markedly in the two groups.

A patient with essential hypertension, who has dyspnea on

exertion and perhaps other symptoms such as fatigue and palpitation, awakens suddenly one night with agonizing shortness of breath which causes him to sit up in an effort to get sufficient air into his lungs. He may even get out of bed or rush to the window for air. This paroxysm of dyspnea is frequently accompanied by cough and it may be by the expectoration of blood-tinged, frothy sputum. When this happens it is definite evidence that pulmonary edema has occurred and indicates clearly the nature of the attack—sudden failure of the left ventricle. If we are fortunate enough to observe the development of an attack we will note frequently an increase of blood pressure prior to the onset, an accentuation of the pulmonary second sound indicating the hypertension in the lesser circulation, and during the attack the presence of numerous moist râles over the bases of the lungs. Not a great deal is known about the actual mechanism of cardiac asthma but we do know that it comes especially at night and it may be that the position of the patient interfering with diaphragm action has something to do with the onset of the attack. Various other circumstances seem to bear a relationship to the attack, such for example as gastric distress, bowel or bladder discomfort, or even an anxiety dream. Cases have been described to me which seemed to follow directly after coitus.

#### FAILURE OF THE RIGHT SIDE OF THE HEART

Both varieties of dyspnea that we have discussed, dyspnea on exertion and paroxysmal dyspnea, are evidences of left heart failure, the one gradual and the other sudden. Meanwhile the right heart is responding by hypertrophy to the increased tension of the lesser circulation caused by the chronic left heart failure. Eventually the right heart fails, unless the individual meanwhile succumbs to an attack of pulmonary edema, coronary occlusion, or some accident unrelated to the heart disease, and then added to the evidences of pulmonary congestion are the signs of increased venous pressure and visceral congestion. That is, we now may observe a little edema of the dependent portions of the body, such for example as ankle edema occurring in the evening, an enlarged and tender liver responsible for indigestion, albuminuria due to renal congestion, and an increased venous pressure which can be observed

as a distention of neck veins or a failure of the arm or hand veins to empty as readily as in the normal individual when the arm is raised above the level of the auricle. At about the same time we may often observe, especially in fluoroscopy, a little fluid at the bases of the chest, obliterating the costophrenic angles. The pulmonary congestion of left heart failure with prominence of the pulmonary conus can also be readily observed fluoroscopically. And of course in time pleural collections may occur as well as abdominal ascites or even a general anasarca. It is important to remember that edema may be accumulating before it manifests itself by pitting and it is also well to remember that in hospital patients or patients who have been in bed for a period of time the edema collects in the dependent portions as for example in the thighs, around the buttocks and in the sacral region. Many other symptoms make their appearance during this period of failure but just how closely they are related to the insufficiency of the heart is a little difficult to state. I am thinking of neurologic and mental symptoms such for example as headache, dizziness, tinnitus and changes in disposition such as irascibility, childishness, fits of depression, persecutory delusions and actual periods of psychosis.

#### ANGINA PECTORIS: PAINFUL HEART FAILURE

And now we must consider an entirely different syndrome that occurs in the course of heart disease associated with essential hypertension. I refer to the condition known as angina pectoris. This syndrome of characteristic pain with typical distribution is sometimes referred to as painful heart failure in contrast to the congestive heart failure that we have just discussed. It is now quite generally accepted that in the majority of instances of angina pectoris, coronary artery disease is responsible. Just why coronary artery disease should be responsible for a painful affection of the heart in one individual and for congestive heart failure in another is not clear. But just as we stated that there are instances of congestive heart failure in the course of essential hypertension that do not show any evidence of coronary artery involvement so there are cases of angina pectoris in which the coronary arteries are free from disease or in which the sclerosis is so slight that it cannot be

held responsible. We presume that vasospasm of the coronary arteries must play a part here. Certainly it is generally accepted that anoxemia of the heart muscle is the mechanism behind the painful affection in the same way that we look upon intermittent claudication as a disorder dependent upon disturbed nutrition and anoxemia of the calf muscles. There are many kinds of precordial pain but there is no mistaking the characteristic attack of angina pectoris. Its association with effort or excitement, its position under the sternum, its characteristic squeezing, constricting or oppressive nature and its well-known distribution, together with associated general anxiety features and the abolition of pain by the use of nitrites make it unmistakable.

### CORONARY OCCLUSION

The profession has also become very familiar with a closely related and even more serious disorder of the coronary arteries and that is sudden occlusion, the result of which is infarction of a portion of the heart wall. The middle-aged, sthenic type of individual with hypertension who develops attacks of angina pectoris is a candidate for an attack of coronary occlusion. The characteristic seizure is now so well known that we need not take time to discuss it. Nor need we for the same reason spend time discussing the differential diagnosis from the upper abdominal emergencies. It is not so well known that another variety of vascular accident often associated with hypertension may be confused with coronary occlusion and that is rupture of the aorta and the formation of a dissecting aneurysm. In this condition the pain is frequently felt in the back, between the shoulder blades or lower as progressive splitting of the aortic coats takes place. Pulmonary embolism with evidence of acute right heart strain now referred to as acute cor pulmonale is sometimes mistaken for coronary occlusion. The similarity may be very close even to the presence of a pericardial friction rub. Spontaneous pneumothorax causing pain and shock has been mistaken for coronary occlusion but once seen is not likely to be again confused. It is well known that the patient with angina pectoris may later develop congestive heart failure following which there is relief from pain. The reverse situation has also been noted, that is, congestive heart

failure that clears up and is followed by angina pectoris. Sometimes pain and congestive failure occur together.

#### THE IMPORTANCE OF PERSONALITY STUDY IN HYPERTENSIVE HEART DISEASE

Although not strictly concerned with the title of this presentation I next want to consider a group of symptoms that may seem to be connected with heart disease occurring in the course of essential hypertension but in reality have nothing to do with the heart. The first is pain in the precordium which must be differentiated from angina pectoris, the second is fatigue that is out of proportion to the amount of physical impairment, and the third is usually described as shortness of breath although it actually is not dyspnea and must not be confused with it. In regard to pain in the precordium in patients with essential hypertension the variety that I speak of does not necessarily occur with exertion but may come on at any time and often does so while the patient is at rest. It is not placed as typically as angina pectoris nor does it have the distribution of true angina. It is frequently described as a soreness or as sticking, burning or lancinating and as one examines the patient the pressure of the palpating hand or of the bell of the stethoscope produces the pain which the patient complains of. Such a pain has nothing to do with coronary artery disease and it is very important to differentiate it. In reality it is a symptom of cardiac neurosis, often erroneously referred to as the effort syndrome. It frequently arises in the course of hypertension because such patients are told that they have heart disease—"an enlarged and leaking heart"—or they suspect, because of common knowledge regarding high blood pressure, that heart disease has developed. A symptom frequently associated is "sighing respiration" which is frequently referred to by the patient as shortness of breath. What the patient really means and will graphically describe is that there is a sense of pressure under the lower part of the sternum which she tries to relieve by taking a deep breath and she sometimes finds herself unable to do so. This is not dyspnea and it has nothing to do with heart failure so that again it is very important to differentiate this symptom. I have been particularly impressed by the presence of these symptoms in women who

have hypertension, especially that variety which appears at the menopause. If we remember, as has so well been pointed out by Levy and Boas, that coronary artery disease is uncommon in women and if we further remember that women seem to stand the effects of hypertension very well we will be on our guard against making a diagnosis of true angina pectoris in a female patient with hypertension. Not that it cannot occur but it is not so common as in men.

These are practical considerations because in studying a patient with essential hypertension it often becomes just as important in one case to reassure the patient in regard to his ability to carry on as it is in another case to urge rest. In order to estimate just how much activity may be permitted or on the other hand how much rest a patient should have we must carefully correlate symptoms, physical signs and laboratory results. This means that physical measurements—blood pressure determinations, heart size, eyeground studies, renal functional estimations—are essential in understanding the physical status of the hypertension patient but that personality studies are equally important in estimating his ability to carry on or his need for restrictions and rest.

#### TERMINOLOGY IN HYPERTENSIVE HEART DISEASE

Lastly, I would like to say something about the term "chronic myocarditis." Fortunately we do not meet it as frequently as we formerly did. In the majority of instances what is called "chronic myocarditis" is hypertensive heart disease either with or without coronary sclerosis. Now while it is true that certain myocardial changes occur under such circumstances which often can be demonstrated by electrocardiographic study this in reality is not a myocarditis although it may be termed "myocardial degeneration." I see no necessity for using the term at all. It is just as simple and much more precise to speak of hypertensive heart disease either with or without coronary artery sclerosis.

In conclusion I have tried to indicate that the ability of the heart to function properly in patients with essential hypertension apparently depends upon the integrity of the coronary vessels. Hypertension can exist without coronary artery sclerosis and of course the reverse is true that coronary artery

sclerosis exists without hypertension but when they coexist the situation is unquestionably more dangerous for the individual. Then it is that obesity, complicating disorders such as diabetes and gallbladder disease, renal impairment and intracranial vascular accident add to the complexity of the problem. Physical and mental stress may act to bring about sporadic increases of blood pressure and thus precipitate heart symptoms either in the form of gradual failure, sudden paroxysmal dyspnea, angina pectoris or coronary occlusion. Sometimes because of the vascular disease that goes on with regard to the other viscera an almost simultaneous disintegration of vital organs occurs. Then it becomes difficult to say whether heart, brain or kidney failure is the cause of death.

We may end this discussion by stating that in the course of hypertensive heart disease, failure of the heart is usually determined by coronary artery sclerosis which impairs the nutrition of the heart muscle. The first symptom is most often dyspnea which occurs on exertion or may occur suddenly—paroxysmal dyspnea (cardiac asthma)—followed by right heart failure producing increased venous pressure, evidences of visceral congestion and edema of the ankles. Quite apart from this congestive heart failure a painful heart affection known as angina pectoris may occur which sometimes is terminated by congestive failure or by coronary occlusion. But coronary occlusion may occur as an independent affection without any history of previous angina. Lastly, either in association with congestive failure or occurring without any clear evidence of heart disease are a number of symptoms which are psychic in origin. They must be sharply differentiated when they exist alone and carefully evaluated when they exist in combination with hypertensive heart disease.

## CLINIC OF DR. MARY HOSKINS EASBY

### PRESBYTERIAN AND WOMAN'S HOSPITALS

---

#### THE EARLY RECOGNITION OF CARDIAC INSUFFICIENCY IN THE PRESENCE OF PREGNANCY

THE importance of the early detection of cardiac insufficiency during pregnancy is emphasized by the statistics of a recent maternal mortality report published by the Philadelphia County Medical Society.<sup>1</sup> In this three-year study there were 69 maternal deaths with heart disease as a factor; in 16 cases heart disease was the primary, in 53 the secondary cause of death. This figure represents 9 per cent of the total deaths of the series. Of the 78 maternal deaths with nonobstetrical conditions as their primary cause, heart disease is second only to pneumonia. From a study by Fraser<sup>2</sup> comes the statement that among all causes of maternal deaths not due primarily to pregnancy, heart disease stands second only to nontuberculous lung disease. Forty of the 69 patients in the Philadelphia County Medical Society report, whose deaths were caused by or complicated by heart disease, had shown complications during previous deliveries. It seems justifiable to conclude from such figures that a substantial improvement in the maternal mortality rate might be effected if this group of cardiac deaths could be eliminated or markedly reduced.

The observations which are presented in this study were made in the cardiac clinics of the Presbyterian and Woman's Hospitals of Philadelphia. The collection of data on pregnant patients was begun at the Woman's Hospital in 1931, and extended through the middle of 1936. At the Presbyterian Hospital observations were made during the years 1934, 1935, 1936. The total number of patients passing through the prenatal clinics of these two hospitals during the years under consideration was 3059; of this number, 258 were referred to

the cardiac clinics for study because of the presence of abnormal cardiovascular signs and symptoms. These patients were all examined before delivery and whenever possible were seen after delivery. When patients failed to return for check-up after their confinements, their hospital records were studied to determine the cardiac diagnoses at the time of their discharge. Those who were considered to have organic heart disease have, with few exceptions, been seen and reexamined at least once since their deliveries; many of them attend heart clinic regularly. Three cases without postpartum data were discarded from the series.

Of the 255 who are included, 42 were found to have organic heart disease; this is 1.37 per cent of the total number of patients passing through the prenatal clinics of the two hospitals. This figure is comparable with the data given by Herrick,<sup>3</sup> who found that 1 per cent of all pregnancies are complicated by cardiac disease, and that 6 per cent of these die. White<sup>4</sup> found that 2 per cent of pregnant women have symptoms and signs of heart disease, and that 1 per cent has organic heart disease. Lamb<sup>5</sup> found organic heart disease in 2.7 per cent of pregnant women in a four-year study. Sodeman<sup>6</sup> states that, in general, the incidence of heart disease in pregnancy is about 1 per cent.

Of the 42 cases, 12 or 28.6 per cent showed some degree of congestive failure during pregnancy or at the time of delivery; the number of deaths was three. A brief review of these cases follows. In making the diagnoses, the functional classification approved by the American Heart Association was used.<sup>7</sup>

**Case I.**—Age twenty-six years. This patient was first seen between the first and second months of her first pregnancy. Her diagnosis was congenital heart disease, pulmonary stenosis, cardiac enlargement, right ventricular preponderance, normal sinus rhythm, Class II B. She was hospitalized during almost her entire pregnancy, and although seen early and presenting evidence of congestive failure during the entire time she was under observation, pregnancy was not interrupted because there was a persistent gonorrheal infection which did not clear up until almost the end of the prenatal period. At times her functional classification was Class III, but adequate therapy

restored her to Class II B; she was allowed to go to term and was delivered with forceps of a normal male child. Some evidence of failure was present during the puerperal period, but this gradually cleared up. This patient attends cardiac clinic regularly. Her present functional classification is II A.

**Case II.**—Age thirty-nine years. This patient showed failure when seen in the seventh month of her ninth pregnancy. She gave no history of failure previously during her long period of childbearing. Her etiology was undetermined; the anatomic diagnosis was cardiac enlargement with mitral insufficiency, left ventricle preponderance; she had a normal sinus rhythm throughout, her functional classification was Class II B. She was hospitalized and given appropriate medication for congestive failure; there was sufficient improvement for the patient to go home until she was at term. She returned to the hospital and was delivered spontaneously. At the time of delivery and during the puerperium she had some decompensation; she has been classed as II B since the time of delivery.

**Case III.**—Age twenty-one years. When first seen she was in her seventh month of her first pregnancy. Her diagnosis was rheumatic heart disease with cardiac enlargement, mitral insufficiency, mitral stenosis, right ventricle preponderance, and auricular fibrillation; she was classed as II B. She was hospitalized a few days after her first examination and remained in the ward until three weeks after delivery, a total of ten weeks. She was given appropriate therapy and at term had reestablished compensation. A cesarean section was done and the patient left the hospital in fair condition. She attends cardiac clinic regularly and still has sufficient cardiac disability to be classed as II B.

**Case IV.**—Age twenty-three years. This patient was three months pregnant when first seen in clinic. The pregnancy under consideration was her second, and she gave no history of failure with the first. She was diagnosed as follows: rheumatic heart disease, cardiac enlargement, mitral insufficiency, mitral stenosis, right ventricle preponderance, normal sinus rhythm; functional classification Class II A. She showed in-

creasing cardiac disability, and the classification was changed to II B within a month after her initial examination. She was hospitalized several days before delivery, and showed improvement with digitalization; a cesarean section was done and the patient was sterilized. Three days after operation she had an acute right-sided heart failure with auricular fibrillation; she recovered from this, and after seven weeks' hospitalization, went home in fair condition. She attends cardiac clinic and is classified as II B.

**Case V.**—Age twenty-five years. She was first seen in the third month of her second pregnancy; no failure had occurred with the first. She was found to have rheumatic heart disease with mitral insufficiency and stenosis and gallop rhythm, and was placed in Class II B. Because of cardiac insufficiency, she was hospitalized ten days before delivery and given appropriate therapy. After compensation was restored, a cesarean section and sterilization were done. She showed some signs of failure during the puerperium, but improved and was sent home in good condition. She attends cardiac clinic, and has remained in Class II A since her discharge from the hospital.

**Case VI.**—Age twenty-one years. This patient, who was first seen in the second month of her second pregnancy, gave no history of previous failure. She was found to have rheumatic heart disease with cardiac enlargement, mitral insufficiency, mitral stenosis, normal sinus rhythm, and she was classified as II B. In addition to signs of congestive heart failure, she had persistent vomiting, weight loss, temperature rise and nosebleeds. Pregnancy was terminated because of rheumatic activity after the patient had been hospitalized long enough for compensation to be restored; she was subsequently sterilized. Her recovery was uneventful. She attends cardiac clinic regularly, and has remained in Class II A since leaving the hospital.

**Case VII.**—Age twenty-one years. This was the patient's first pregnancy and she was in her sixth month when first seen. She was found to have rheumatic heart disease with cardiac

enlargement, mitral insufficiency, mitral stenosis, with normal sinus rhythm. She was in marked failure, Class III, and was hospitalized. She improved on appropriate medication and was permitted to go home on a strict regimen of rest and digitalis. Later in her pregnancy it was necessary to hospitalize her again for seven days; she again improved, went to term, and was delivered by a cesarean section. Sterilization was done, and subsequently the patient left the hospital with compensation reestablished. No follow-up examination has been possible.

**Case VIII.**—Age twenty-seven years. This patient was first seen in the seventh month of her second pregnancy. Her diagnosis was rheumatic heart disease, cardiac enlargement, mitral insufficiency, a slight degree of coronary sclerosis, normal sinus rhythm, Class II B. She gave a history of having had sufficient cardiac disability with the first pregnancy, to have needed bed rest for a period of several weeks and delivery by cesarean section. In the pregnancy under consideration, she was carried along to term and was delivered by forceps of a stillborn child. Later she came in near the end of her third pregnancy and was hospitalized and delivered by cesarean section because of evidence of congestive failure and small measurements. Her recovery was uneventful and she left the hospital with compensation restored. Unfortunately this patient has been lost sight of, and no follow-up examination was possible after discharge from the hospital.

**Case IX.**—Age thirty-two years. This patient was first seen between the seventh and eight months of pregnancy. She had rheumatic heart disease with cardiac enlargement and mitral stenosis, and showed definite evidence of myocardial fibrosis by electrocardiogram; she had normal sinus rhythm and was classed as II B. She had had 4 previous pregnancies, but gave no history of previous failure with any of them. She improved with rest and digitalization, and about 1 month after her first cardiac examination, labor was induced. Her recovery was uneventful. About ten days later she was sterilized; she recovered and left the hospital in good condition and has shown no evidence of failure since.

**Case X.**—Age twenty-eight years. This patient was first seen between the fourth and fifth months of her fifth pregnancy. She had rheumatic heart disease with cardiac enlargement, mitral insufficiency, mitral stenosis, sino-auricular tachycardia; she was in advanced failure (Class III), with a marked degree of pulmonary edema. She was immediately hospitalized and digitalization begun. Later on the same day of her admission to the hospital she had a premature separation of the placenta followed by death.

**Case XI.**—Age nineteen years. This was the patient's first pregnancy. She was first examined at six months and found to have rheumatic heart disease with cardiac enlargement, mitral insufficiency, mitral stenosis, early aortic insufficiency, and a possible adherent pericardium. The electrocardiogram showed normal sinus rhythm interrupted by auricular premature contractions and right axis deviation; she was classed as II B. She was put on a strict regimen of rest and digitalis with frequent reexaminations in clinic; no definite failure occurred during this period. At eight and one-half months she was admitted to the hospital for observation, and after about two weeks of complete rest, a cesarean section was performed. The patient had a cardiac arrest on the operating table but recovered. Following this she developed auricular fibrillation, and for three days her progress seemed fairly satisfactory under digitalis therapy. She then developed a *Staphylococcus aureus* blood stream infection and died ten days after operation.

**Case XII.**—Age twenty-five years. When this patient first came under observation she was five and one-half months pregnant; she had had no previous pregnancies. She was found to have rheumatic heart disease, cardiac enlargement, mitral insufficiency, mitral stenosis, right ventricular preponderance, normal sinus rhythm, and she was put into Class II B. She was followed for a month and a half in clinic during which time she presented no definite evidence of failure. At seven months she went abruptly into failure with an attack of nocturnal dyspnea; unfortunately she did not report to the hospital until four days later at which time she was in advanced

failure (Class III). She was then admitted to the ward and an effort was made to digitalize her. Her condition was too serious to permit of interruption of pregnancy. Digitalis and bed rest failed to restore compensation in any degree and four days after admission she delivered spontaneously and the following day died in failure.

In this group of 12 cases presenting cardiac failure, one was first seen between the first and second months of pregnancy, 2 were seen at three months, 1 at four months, 1 at four and one-half months, 1 at five and one-half months, 2 at six months and 4 at seven months; 5 were primiparae, 4 were Gravida II, 2 were Gravida V, and 1 was Gravida IX. Only 1 of the multiparae had any history of failure with previous pregnancy; 11 were considered to have sufficient cardiac disability to be classed as II B at the time of their initial examination. The one who was in Class II A at the beginning of the observation period (three months) had gone into Class II B a month later. All but 2 had definite rheumatic histories, of these 2, one had a congenital lesion and the other gave no history of disease predisposing to organic cardiac change.

There were 3 deaths in the groups. Two of these, the one associated with the *Staphylococcus aureus* septicemia, and the one with the premature separation of the placenta, cannot be attributed to congestive heart failure alone, inasmuch as the associated conditions themselves carry a high mortality rate; the third case was one of uncomplicated congestive heart failure. We find, therefore, in this group that the percentage of patients dying of congestive failure alone is 8.33 of all who were in failure, and 2.38 of the entire organic group of 42 cases. This figure seems low, inasmuch as Herrick<sup>3</sup> states that 6 per cent of pregnant women with heart disease die; and Eastman<sup>8</sup> gives a mortality rate of 5 to 8 per cent after a widespread study in hospitals with and without special cardiac clinics. The explanation for this apparent low figure in my series is that cardiac death may occur during pregnancy or delivery without failure being present, and would therefore not be included in this study. Such cases would be death from emboli, from subacute bacterial endocarditis, etc. Also in the group of 42 organic cases studied, all except 6 were under close observation of both prenatal and cardiac clinics during that

part of pregnancy in which failure is most apt to occur, namely, the last two months. Whenever indicated, these patients were hospitalized for rest and observation, or put to bed at home under a regimen of rest and medication. One death occurred in the organic group which was not mentioned above because no failure was present; this case was one of rheumatic heart disease with mitral stenosis whose death occurred four days postpartum from a *Staphylococcus aureus* blood stream infection, but whose functional classification remained II A throughout the period of observation. This case added to the 3 already discussed gives us a total of 4 deaths associated with cardiac disease, but in 3 of which death could not be attributed to heart disease alone.

It would be justifiable to conclude that close observation in cardiac clinic as well as in prenatal clinic of the cardiogravid patient during pregnancy is a factor in reducing mortality from congestive failure. It enables the early signs and symptoms of failure to be detected and evaluated, and adequate treatment instituted. The detection of early failure in these patients is not without difficulty; Gammeltoft<sup>9</sup> states that 16.3 per cent of 239 normal pregnant women studied had signs and symptoms of heart disease; all of which cleared up soon after delivery, and did not improve on rest and digitalis. Hamilton and Kellogg<sup>10</sup> state that 7.5 per cent of all pregnant patients in a group they studied required a decision on the heart. The signs and symptoms presented by the noncardiac pregnant patient depend on the fact that new demands are made in pregnancy on circulation, and consequently on the heart. Stander and Cadden,<sup>11</sup> using the acetylene method of computing cardiac output, found an increase in cardiac output of more than 50 per cent in the latter half of pregnancy. Grollman<sup>12</sup> points out that there is a large increase in the area of the circulatory bed in pregnancy. In order to maintain a constant blood pressure without depriving other parts of the body of a normal blood flow, there must be an increased cardiac output. This suggests that the heart must hypertrophy during pregnancy, and brings up the disputed point of whether the enlargement seen in the latter months is actual or whether the organ seems enlarged because of a pushing upward by the gravid uterus with outward displacement of the apex impulse and frequently

with a marked degree of left axis deviation in the electrocardiogram. In any event, it is to be expected that a heart which has sustained damage from infection, and which has consequently a diminished reserve, will manifest evidence of disability more readily under the strain of pregnancy than an undamaged heart. Consequently the earlier in pregnancy failure appears the more serious is the outlook. It is therefore essential that patients with definite organic damage be seen as early as possible for cardiac study, that they report for reexamination at regular intervals during pregnancy, that they be seen during their hospitalization by a cardiologist when possible, and that they be referred back to cardiac clinic for postnatal check-up. This requires the closest cooperation between the obstetric and cardiac departments of the hospital.

As has been pointed out, symptoms of early cardiac insufficiency may appear in pregnant patients who have no organic cardiac disease. Of the group of patients studied by me, the 213 who were not included in the organic group, showed the following signs and symptoms: 139 had systolic murmurs at the apex or pulmonic areas, 114 had dyspnea, 7 had orthopnea, 67 had palpitation, 12 had definite edema.

The early detection of congestive failure in pregnancy depends, therefore, on the finding of those same classical manifestations of cardiac insufficiency as would be seen in a non-gravid cardiac patient, namely: dyspnea, orthopnea, easy fatigability, palpitation, edema, the appearance of a systolic murmur, cardiac enlargement, premature beats, engorgement of the neck vessels, etc. But in addition, each symptom and sign must be evaluated in the light of the gravid state, and the degree to which it is intensified as pregnancy advances be taken as a criterion of its prognostic value. The appearance of pulmonary edema, gallop rhythm, auricular fibrillation, paroxysmal nocturnal dyspnea, severe precordial or substernal pain or rheumatic activity, is always an indication of serious trouble. History in these cases is of the utmost importance. Since the etiologic factor in the great majority of these cases is rheumatic, a painstaking search for the history of past infections must be made. If found, such a positive history increases the likelihood that the abnormal cardiac findings are on an organic basis, and both treatment and prognosis must be

modified accordingly. When the patient gives a history of one or more breaks in compensation, the expectation of failure during pregnancy is greatly increased.

In considering treatment of heart failure in pregnancy, it must be kept in mind that pregnancy is a strain on the circulation, and when heart disease is present, pregnancy may precipitate failure where failure would not occur were pregnancy not in the picture. The first consideration under treatment, therefore, is prevention. Patients who are in failure or have had previous failures, either with or without pregnancy, must be prevented from undertaking motherhood. This same is true of patients with rheumatic activity, subacute bacterial endocarditis, or fixed hypertension. One cannot state that failure may be anticipated in the presence of certain valvular lesions and not in the presence of others. In my group of 29 organic cases in whom no failure occurred, 11 had well established mitral stenosis, and 1 had an aortic insufficiency associated with mitral stenosis. I believe that where mitral stenosis has been of such long standing that the cardiac reserve is definitely impaired, it should contraindicate pregnancy. If it is accompanied by auricular fibrillation, pregnancy should certainly be forbidden even where there is no definite failure, as there is always danger of fatal emboli. Aortic insufficiency is considered by some as a contraindication. In my series, 2 patients had this lesion, both associated with mitral stenosis; 1 did not go into failure, the other died in failure, but had also a positive blood stream infection.

I believe that prevention should extend to this length: that any pregnant patient with definite organic heart disease should be regarded as a potential case of failure because of the added burden which the gravid state places on an already impaired circulation, and because there is no known formula which will tell us which cases will go to term safely and which will not. In addition, there are many women with organic cardiac disease who may go through pregnancy safely, but who sustain greater impairment to their already damaged hearts as a result of it. Lamb<sup>5</sup> reports from a study of 50 cases of organic heart disease, over a four-year period, that 43 per cent of them were made worse by the ordeal of pregnancy. Where there is organic cardiac disease of such a nature as is known

to impair cardiac reserve, the patient should be warned before undertaking motherhood that her pregnancy and delivery will be fraught with risk. If she has passed through previous pregnancies safely, she should be advised strongly against undertaking another one, and if she has passed through previous ones with cardiac difficulty, further pregnancies must be forbidden.

The treatment of early failure in pregnancy is the same as in the nongravid state. Rest is of course the first therapeutic measure to be enforced. Rest in the hospital is preferable to rest at home in the majority of cases. Hamilton and Kellogg<sup>10</sup> state that "if a patient with heart disease develops decompensation during pregnancy, she belongs in a hospital until pregnancy is terminated." Digitalis therapy should be employed, the dosage being adequate to control the heart rate at 80 or below. If the patient improves on rest and digitalis, she may gradually be worked up to mild activity. If allowed to go home, she must be on a regimen of rest and a maintenance dose of digitalis; such patients should return for hospitalization ten to fourteen days before term. If there is no favorable response to these measures and failure progresses, further treatment will depend on the stage of pregnancy. Each case must be studied as an individual problem in determining whether or not, and when, pregnancy should be terminated. Pardee,<sup>13</sup> writing on conditions indicating therapeutic abortion, states that patients seen before the fourth month in Class II B or III, should be considered for therapeutic abortion. He says: "It should never be performed, however, until after a proper course of treatment by rest and digitalis. Such patients are always improved by this to some extent at least, and after improvement has progressed as far as it will, and there has been no further improvement for two weeks, it is time to decide on further management." Should abortion be decided upon, the method of choice must next be considered. During the first three months vaginal procedures apparently do not greatly disturb circulation, but from five to seven months the heart is probably less disturbed by abdominal operation. The choice of anesthesia presents another problem. Local anesthesia is of course the safest procedure if the patient is cooperative; on the other hand, cardiac patients stand ether well.

If the patient's failure can be controlled and she is carried on to term, cesarean section seems to be the method of delivery most advantageous because it permits of sterilization, avoids physical strain and also because it can be performed at a time which is optimum from the cardiac standpoint. On the other hand, the recovery stage from a nonoperative delivery is shorter. Hamilton and Kellogg<sup>10</sup> do not believe it is justifiable to do a cesarean section for the sake of sterilization on account of the greater risks of this method. They state that the majority of multiparous cardiacs are safest delivered by forceps at full term with sterilization some months later if desirable. Should the patient be delivered by the usual method, and should some cardiac insufficiency be present, it is important that her head be kept elevated throughout delivery, and that the second stage of labor be shortened and eased in every way possible.

The success of the treatment of congestive failure depends not only on early detection, but upon such other factors as the economic status of the patient, her intelligence and ability to cooperate, her religious affiliations, the avoidance of intercurrent infections, the willingness of the hospital to keep a patient with poor home conditions in the ward for weeks or even months of rest if necessary, and the absolute cooperation between the obstetrical and cardiac departments. Each case requires individual study and care. All the above-mentioned factors must be considered of the greatest importance if our efforts to reduce the mortality from cardiac disease in general and most particularly from congestive heart failure are to meet with success.

## CLINIC OF CHARLES L. BROWN

TEMPLE UNIVERSITY SCHOOL OF MEDICINE AND TEMPLE  
UNIVERSITY HOSPITAL

---

### USE OF DRUGS IN CARDIOVASCULAR DISEASE

THE significant clinical developments in the course of cardiovascular disease which are influenced by the use of drugs may be listed as of three types; namely, congestive myocardial failure, cardiac pain, and abnormal heart action. Although some of these clinical features may be present more commonly in certain forms of heart disease, one or more of these conditions may occur in most any type of cardiovascular disease, and the treatment of them is essentially the same, irrespective of the etiology of the heart disease. The use of drugs, then, in patients presenting these features, may be considered as treatment indicated by symptoms and signs.

For the purpose of the subject under discussion cardiovascular disease is divided etiologically into five groups; namely, rheumatic heart disease, hypertensive heart disease and coronary arteriosclerosis, thyrogenic heart disease, syphilitic heart disease, and subacute bacterial endocarditis. Then, accordingly, the drugs used in the different types of heart disease should be referred to as treatment indicated by etiology.

#### I. TREATMENT INDICATED BY SYMPTOMS AND SIGNS

##### 1. CONGESTIVE MYOCARDIAL FAILURE

**Digitalis.**—Digitalis, the most useful drug in the treatment of congestive myocardial failure is especially efficacious in those cases in which auricular fibrillation with a high ventricular rate is also present. However, it has been demonstrated adequately that very satisfactory results can be obtained in cases of cardiac decompensation with regular

rhythm. Hypertension in itself is no contraindication to digitalis therapy.

The plan of digitalis administration should vary somewhat with the individual patient. First, one should determine whether the patient has had any digitalis within the past three weeks, and how much if possible, and if the patient has had digitalis during this time further digitalis should be given in smaller doses and more cautiously. If no digitalis has been given within three weeks, or the patient has never had any digitalis the decision rests between rapid digitalization in a few hours by massive doses and slower digitalization by smaller doses at less frequent intervals during the next three or four days or longer. A severe degree of decompensation in a patient who has had no digitalis is the prime indication for rapid digitalization, while slow digitalization may have some advantages in the milder form of decompensation or in the patient who has had a considerable or an unknown amount of digitalis.

At a time when the massive dosage method was first coming into wide use, inadequate results from digitalis were attributed to insufficient digitalis and properly so. No doubt the potency of many digitalis preparations was less certain then than now. The common method of calculation of the digitalization dose was on the basis of body weight, using such formulae as 30 mg. of digitalis folia, or its equivalent, per kilogram of body weight, or 1 grain per 5 pounds of body weight. Accordingly, for a patient weighing 154 pounds the calculated dose would be 2 Gm. or 31 grains of digitalis folia, or its equivalent. The dosage might be expressed in terms of cat units, the "cat method" being commonly accepted for pharmacologic assay, and 1 cat unit representing  $1\frac{1}{2}$  grains, the above total dosage being equivalent to approximately 20 cat units. Ordinarily, one quarter of the digitalization dose (in the above instance  $7\frac{1}{2}$  grains or 0.5 Gm.) was given for 3 doses, about four to six hours apart, making three quarters of the calculated dose received by the patient within an eight- to twelve-hour period. By this time some effect would be noted probably as diuresis from digitalis usually does not occur in any marked degree until two thirds to three fourths of the digitalization dose is given, and by this time some effect upon the pulse rate or digestive tract might be looked for. If the optimum effect were

not noted  $1\frac{1}{2}$  grains (0.1 Gm.) to 3 grains (0.2 Gm.) one to three times a day would be given until beneficial effect was obvious or early toxic effects resulted. A good therapist would get the desired effects but stop short of toxicity, fulfilling the directions of Withering: "Let the medicine be continued until it either acts upon the kidneys, the stomach, the pulse or the bowels; let it be stopped upon the first appearance of any one of these effects."

This method of administration is satisfactory for hospital practice or very carefully controlled house practice, but in cases where such close observation is not possible it has become common practice to count on the average optimum amount of digitalis for the averaged-sized adult (150 pounds) as about 20 grains of digitalis folia, or its equivalent in other preparations, given in divided doses as above stated, and to proceed to satisfactory digitalization from that point cautiously up to the maintenance dose.

Two factors enter into this problem; first, it is almost impossible to gage the dosage accurately by the body weight as a considerable portion of the body weight may be edema fluid, and second, the maintenance dose may be greatly different in individual cases. Usually, however, the patient will know something about his weight before the edema appeared or some estimate of the weight representing edema may be attempted, and calculation can be made accordingly. In general,  $1\frac{1}{2}$  grains of digitalis folia (or its equivalent) has been found to be the average maintenance dose, but it should be known that some cases are well maintained on less ( $\frac{3}{4}$  grain) or more (2 grains) than this, and only close clinical observation will control this factor.

Four methods of administration are available; namely, the oral, the subcutaneous, the intravenous, and the rectal. Only in very rare instances need any other than the oral route be employed. Digitalis folia and tincture of digitalis are entirely satisfactory for oral administration and, except in very unusual instances are there any obvious advantages of other preparations. An injectable form for intravenous and subcutaneous administration is necessary in cases demanding quick action and many proprietary preparations are now available in properly standardized forms, and the future promises more

stable solutions of this type. General principles of assay and dosage expressed above are sufficient in guiding treatment if dependable and in-date preparations are used. It is well to remember that tincture of digitalis, or other solutions of digitalis are almost as efficacious if given by rectum as by mouth, usually some dilution with normal saline being desirable.

If slower digitalization is employed a satisfactory method is to use  $1\frac{1}{2}$  grains or 3 grains, depending on rapidity desired, of digitalis folia three times a day until the therapeutic effect is obtained and then giving a daily maintenance dose. In using digitalis in the presence of thyrotoxicosis or pneumonia or any other toxic state it is advisable to give only about half of the calculated dose for digitalization and then proceed cautiously, as it may be difficult to differentiate any increased toxicity as due to the digitalis or change in the preexistent toxic condition.

Clinically it seems to make no difference in the average case whether digitalis folia or the tincture is used providing potent and well standardized fresh preparations are employed and given in sufficient doses. There is a fallacy in the suggestion that the dosage can be more accurately gaged with tincture as the individual dose may be varied by as little as 1 drop. Usually it is not possible to determine the optimum amount by such small margin and there is no practical advantage in attempting to do so. It should be remembered that a drop of tincture of digitalis from the average dropper is less than a minim (usually about 2 drops to the minim) and the only dependable way is to measure the dose in minims.

Other drugs in the digitalis series still in use are strophanthus, ouabain, squills, and apocynum. These drugs seem to present no clinical advantage over digitalis, and since digitalis preparations now are so dependable it seems much wiser in average practice to know how to give digitalis and use it. Perhaps on rare occasions strophanthin or ouabain should be used when the digitalis effect must be obtained very promptly as a life-saving measure, but these drugs need no consideration in the ordinary management of congestive failure. Except in very rare instances there seems to be no good reason to prefer some of the glucosides of digitalis, although advantages are claimed by some. Verodigen, a gitalin- or digitalein-

like fraction of digitalis is an example, said to be more readily absorbed than digitalis, and claimed to be better tolerated by the gastro-intestinal tract, but its potency,  $\frac{1}{240}$  grain of verodigen being equivalent to  $1\frac{1}{2}$  grains of digitalis folia, indicates the advisability of its use in specially selected cases and under facilities for very careful observation.

**Diuretics.**—Diuretics are valuable adjuncts to digitalis therapy and three general groups are available: the xanthine derivatives, certain mercury compounds, and several salts. One of these diuretics may be helpful when another has failed, or a combination may act favorably when no appreciable effect has been obtained by one or the other alone. The presence of gastro-intestinal symptoms, the necessity for prompt diuresis, the definite accompaniment of nephritis, and the physician's personal preference are factors that influence the choice of one or other of these diuretics in the beginning. Failure of this choice leads to trial of others or combinations.

Theophylline (theocin), theobromine sodium salicylate (diuretin), and theobromine calcium salicylate (theocalcin) are the commonly used representatives of the xanthine derivatives. These three often produce excellent diuresis, and all are better given in fairly large doses for a short period of time and repeated, than in small doses over a long period of time. These drugs, especially theophylline, may produce gastric irritation or mental aberration, but not commonly, and such occasion need cause no alarm as discontinuance of the drug is accompanied by fairly prompt clearing of these symptoms. Theophylline in doses of 5 to  $7\frac{1}{2}$  grains (0.3 to 0.5 Gm.), or theobromine sodium salicylate,  $7\frac{1}{2}$  to 10 grains (0.5 to 0.6 Gm.), or theobromine calcium salicylate, 15 grains (0.1 Gm.) three times a day for two days or 6 doses, usually proves a satisfactory way to give these drugs. If diuresis is to occur from the drug it will do so likely by this time. Although these three drugs all belong to the same group, occasionally one will produce a diuresis in the same patient who has had no appreciable effect from one of the other two.

The mercurial diuretics are very important in the treatment of congestive failure and properly have enjoyed widespread clinical use. Merbaphen (novasurol, a mercury urea compound), mersalyl (salyrgan, a mercury salicylate com-

pound), and mercupurin (a mercury theophylline compound), are the three representatives of this group. These drugs are prepared for clinical usage as a solution in glass ampules, to give 1 cc. to 2 cc., preferably intravenously, or intramuscularly, but never subcutaneously. Subcutaneous injection or leakage about the point of injection into the vein causes necrosis of tissue, so extreme care about injection is necessary. The use of a small caliber needle and dilution of the drug before intravenous injection are helpful in avoiding such accidents. A great deal has been written about the relative toxicity especially of the first two of these mercurials mentioned; the approximate percentage of mercury in the three compounds is: novasurol, 33.9 per cent, salyrgan, 39.6 per cent, and mercupurin, 41 per cent. One gathers the impression from the literature that salyrgan is less toxic than novasurol, and that mercupurin is no more toxic than salyrgan, and possibly less so. The two main factors thought to influence this apparent paradox are individual sensitivity to mercury, or greater tolerance by some patients, and the possibility that the toxicity depends on the chemical linkage of the mercury to the rest of the molecule rather than to the actual percentage of mercury present. While there is no clear preference of one of these drugs over the other, on the whole, clinical reports have seemed more favorable to the use of salyrgan or mercupurin. Clinical doses of these mercurials may be accompanied by some increase in the casts in the urine, and because of the effect of mercury on the kidney, their use in patients with nephritis is cautioned. However, in ordinary cases of congestive failure their use need not be curtailed, as the kidney irritation as determined by the urinary cast count quickly subsides, and the gravity of the situation justifies their use.

Salyrgan and the mercurial salt of mercupurin (mercurin) are now available in suppository form and these preparations produce diuresis comparatively favorable with the intravenous administration.

If these diuretics are effective the diuresis will occur within a few hours, so it is advisable to give the drug early in the morning, so as to least disturb the patient at night. The dose of any of these ordinarily used is 1 cc. to 2 cc.; it may be repeated in one week, or if occasion demands as often as twice

a week. In some instances the mercurials have been efficacious, when they have not been before, after three or four days taking 60 to 90 grains (4 to 6 Gm.) of ammonium chloride daily.

**Certain Salts.**—The acid-producing salts, calcium chloride, ammonium chloride, and ammonium nitrate, may serve as excellent diuretics when given in large doses, ranging from 90 to 180 grains (6 to 12 Gm.) daily. Ammonium chloride or ammonium nitrate is more commonly used, and is best given in enteric-coated pills in an effort to avoid gastric irritation. These drugs may be given in capsules with the meals. If they are to be given in liquid form a vehicle containing yerba santa makes the preparation more tolerable. At times a better diuretic effect is noted by giving these salts in the above doses for a few days then discontinue them for a few days. A neutral diet aids in decreasing the amount of the salt necessary, but this is difficult to follow out for longer than a few days unless dietetic service is available.

Potassium nitrate or potassium chloride in large doses, 120 to 180 grains (8 to 12 Gm.) daily have been found to produce satisfactory diuresis in many cases, caution being given in cases with severe renal insufficiency.

**Morphine and Sedatives.**—These drugs are very useful in the cardiac patient, to give them mental and physical rest, and morphine sulfate is especially effective in the acute distress of congestive failure, when used in moderate doses.

**Cathartics.**—In some instances cathartics, especially the salines, are very useful, but generally the extra effort of increased bowel movements is undesirable if other measures are effective.

In the foregoing discussion no distinction has been made between so-called "right ventricular failure" and "left ventricular failure," although the general picture of congestive failure represents essentially the result finally or predominantly of "right ventricular failure." Attention should be called to the acute paroxysmal dyspnea with or without "cardiac asthma" due to acute failure of the left ventricle. Morphine sulfate is indicated in such an attack; aminophyllin, intravenously, may be helpful; and in those cases tending to have associated "cardiac asthma" with pulmonary edema the mercurials may be of some value.

Aminophyllin, 0.24 Gm. (4 grains) given slowly intravenously, is very effective in relieving the acute distress of Cheyne-Stokes respiration, and an oral dose in the evening may prevent occurrence at night, or steady dosage of  $1\frac{1}{2}$  grains three or four times a day may offer freedom from this symptom.

## 2. CARDIAC PAIN

The most significant cardiac pain is that of angina pectoris and coronary thrombosis. Although of similar character in onset, location and distribution the treatment of the two is different in the use of the vasodilators. The vasodilators are contraindicated in coronary thrombosis, as shock is a part of the picture. The blood pressure as a guide will help to avoid giving the nitrites when the diagnosis may not at first be apparent.

The nitrites, theobromine sodium salicylate, and aminophyllin are the drugs of choice for angina pectoris. Of the nitrites, nitroglycerin and amyl nitrite are the quickest and shortest in action and therefore useful in the acute attack. Sodium nitrite and erythrol tetranitrate are more useful in an attempt to decrease the frequency and severity of the attacks. The same may be said of aminophyllin and theobromine sodium salicylate; aminophyllin is given in doses of  $1\frac{1}{2}$  to 3 grains (0.1 to 0.2 Gm.) three times a day or sometimes  $1\frac{1}{2}$  grains five or six times a day is more effective. Theobromine sodium salicylate is given much the same way, the dose being  $7\frac{1}{2}$  grains (0.5 Gm.).

For coronary thrombosis morphine sulfate and aminophyllin are more effective. Morphine sulfate may and should be given in large doses, in the severe case  $\frac{1}{2}$  grain hypodermically being justified. Aminophyllin, 4 grains (0.24 Gm.) intravenously, is frequently attended by more prompt and greater relief than is morphine sulfate. It should be given slowly; if the pain recurs after a few hours it is permissible to repeat the dosage. Aminophyllin,  $1\frac{1}{2}$  grains (0.1 Gm.) by mouth three or more times a day, is recommended routinely in coronary thrombosis for an indefinite time.

Of the drugs, sedatives play an important part in the relief of painful discomfort over the heart, due to other forms of heart disease; or treatment of the primary conditions is indicated if other than cardiac in origin.

## 3. ABNORMAL RHYTHM OR RATE

From the standpoint of general practice the following arrhythmias are the most important as they can usually be recognized at the bedside and often are amenable to treatment; ventricular extrasystoles, auricular fibrillation, auricular flutter, paroxysmal auricular tachycardia, ventricular tachycardia and complete heart block. Extrasystoles unless frequent and accompanied by palpitation or precordial discomfort rarely call for treatment, but if so, sedatives should be first of the drugs used. Very rarely it may be necessary to use quinidine sulfate or digitalis in trying to stop them. The principles in giving these two drugs is the same here as on other occasions of their use, except usually smaller and less frequent doses are necessary. If the extrasystoles first appear while the patient is under digitalization they probably signify digitalis effect.

Auricular fibrillation and auricular flutter may be discussed together because two drugs are useful in both instances; namely, digitalis and quinidine sulfate. Digitalis is indicated in auricular fibrillation, unless perhaps in the case of "slow" fibrillation without congestive failure. Digitalis does not stop fibrillation but decreases the pulse deficit and the ventricular rate. All patients with auricular fibrillation should not be given quinidine sulfate, especially those with fibrillation of long standing. Quinidine sulfate is best indicated in the case of short duration, without congestive heart failure, and with a ventricular rate under 110. The auricular fibrillation of thyrogenic origin is especially suitable for quinidine sulfate therapy. Special caution is urged in the long-standing fibrillation with congestive failure of some duration, and quinidine sulfate will probably do no good anyway. Frequently it is advisable, especially in rapid fibrillation, to digitalize the patient before giving the quinidine sulfate. Digitalization and quinidine sulfate are advisable in auricular flutter and return to normal rhythm may be expected.

Quinidine sulfate should be given first in a test dose of 3 grains to note any untoward effects of susceptibility. If any serious toxic effect occurs it is likely to be one of respiratory failure and caffeine sodium benzoate, 15 grains, should be given intravenously immediately, and artificial respiration if neces-

sary. When the patient is known not to be susceptible, the quinidine sulfate may be given in 6-grain doses every four hours until rhythm is restored. Larger doses more frequently may be used if close observation and electrocardiographic control are available. Another often satisfactory clinical method is to give 3 doses a day, increasing the dose for each succeeding day by  $1\frac{1}{2}$  grains, as for example, 3 grains three times a day, then  $4\frac{1}{2}$  grains three times a day the next day, and so on. Usually it is not wise or necessary to give higher doses than  $10\frac{1}{2}$  or 12 grains three times a day.

If vagal or ocular pressure has not stopped an attack of paroxysmal tachycardia, three drugs may be considered: quinidine sulfate, digitalis, and acetyl- $\beta$ -methylcholine chloride (mecholin or mecholyl). The dosage of the acetyl- $\beta$ -methylcholine is 15 to 20 mg. subcutaneously. Atropine sulfate will counteract any untoward effect of the acetyl- $\beta$ -methylcholine. If attacks are frequent quinidine sulfate, 3 grains one to three times daily, may be useful in preventing recurrence. Sedatives are suggested also to relieve anxiety and promote rest.

Ventricular tachycardia is a dangerous arrhythmia and often responds satisfactorily to quinidine sulfate therapy, large doses and even intravenous use of quinidine sulfate being justified in some instances.

The drugs of use in complete heart block are epinephrine hydrochloride, ephedrine sulfate, barium chloride, and possibly atropine sulfate. Epinephrine hydrochloride, 5 to 15 minims of 1:1000 solution hypodermically or intracardiac, is used for the attack of Adams-Stokes syndrome, while ephedrine sulfate,  $\frac{3}{8}$  grain by mouth one to three times daily, may help in preventing severe and frequent attacks. Barium chloride,  $\frac{1}{2}$  grain by mouth, three or four times a day, is sometimes effective in preventing attacks.

## II. TREATMENT INDICATED BY ETIOLOGY

In rheumatic fever the salicylates still remain the therapeutic stand-by as far as drugs are concerned. The newly used drug, sulfanilamide (para-amino-benzene-sulfonamide, prontosil), offers some promise, but its effectiveness in rheumatic fever must await further observation. In hypertensive heart disease and coronary arteriosclerosis any drug therapy at

present is entirely for symptomatic relief. Thyrogenic heart disease is of two varieties, the so-called "myxedema heart" and thyrotoxic cardiac disturbances. When congestive failure appears, its management is the same as in other instances. Desiccated thyroid gland in sufficient quantity to correct the myxedema improves the heart condition providing arteriosclerosis and resultant myocardial changes are not too great, and these very features may in a way influence the amount of thyroid the patient can take without producing angina pectoris or other symptoms of too great cardiac activity in a heart long unaccustomed to it. In the thyrotoxic case iodine in some form is a part of the program for preoperative preparation. When syphilis is the etiology of cardiovascular disease, alone or with associated arteriosclerosis, arsenic, mercury, bismuth and the iodides in their various forms must be considered. More often the problem is one of syphilitic aortitis with or without aortic valvular disease rather than actual syphilis of the heart. By the time these cases have a predominant cardiac phase the matter of treatment is not so much specifically against the spirochete as against the damage it has caused. In such cases the arsenicals are used only after careful consideration of the individual case, then with caution. No effective drug treatment of subacute bacterial endocarditis (*Streptococcus viridans*) is known.

## CLINIC OF DR. GEORGE C. GRIFFITH

### PRESBYTERIAN HOSPITAL

#### DIET IN THE TREATMENT OF HEART DISEASE

THE intent of this paper is twofold: first, to show the purpose of diet regulation in heart disease; second, to give specific directions for diet management: (a) in organic heart disease prior to the onset of failure, (b) in congestive heart failure, (c) in the acute cardiac accidents, and (d) during the convalescent period.

Diet regulation in heart disease has but one purpose; *i. e.*, the *lessening of the work demand of the heart*. There are two ways by which this can be accomplished; first, by restricting the intake sufficiently to maintain normal weight and nutrition; and, second, by avoiding those foods which directly or indirectly stimulate the heart, and those foods which increase the work demand by prolonging or impairing the digestive process.

The nutrition of the body tissues, the weight of the body, and the etiologic factors causing the heart disease, must be considered when approaching the problem of lessening the work demand upon the heart. For example, weight reduction is often considered essential in cardiac management, because it is generally conceded that the sheer bulk of inert material increases the work demand of the heart. Under normal conditions of muscular development, there is a ratio of development maintained between the myocardium and the skeletal muscle; but this ratio is not true when weight increase results from the fat. There is no compensatory increase in the strength of the heart, and this organ is forced to labor under a serious handicap. Because of the discomfort to the obese patient from the circulatory embarrassment, lack of exercise

leads to further increase of weight, adding an additional burden on the heart.

Food restriction is of importance not only for the correction of obesity, but also because of the influence certain foods possess in increasing the work demand of the heart. The brilliant results which have been achieved in restoring compensation in a failing heart by thyroidectomy, give evidence of the extent to which we can lessen the work demand of the heart by slowing down the metabolic rate. A similar effect can be obtained, in some measure at least, by the restriction of protein, and thus reducing that stimulus to metabolism known as the specific dynamic action which comes from this important component of every diet. It is definitely demonstrated that protein foods cause an acceleration of surprising magnitude and duration; and that a meal of 50 Gm. of protein throws an extra burden of work on the heart equivalent in energy output to four hours of cardiac work under fasting conditions. With an impaired myocardium it is important to give a patient sufficient of this necessary food element, namely, protein, to meet nutritional needs; *i. e.*, approximately 0.6 Gm. per kilogram of body weight or about 50 Gm. per day for the average individual. This provides a margin of safety, but does not increase the specific dynamic action necessary to maintain nutritive needs, and the patient avoids the danger of an unduly accelerated metabolism. Proger proposed, therefore, to obtain the good results obtained by thyroidectomy by semistarvation, reducing the metabolism, the blood pressure and the pulse rate. Some surprising results have already been obtained.

Carbohydrate is the most readily utilizable fuel to furnish the contracting heart muscle the material to produce energy. Since a damaged heart is already laboring under a handicap, it should be furnished with this easily utilizable fuel in large amounts. Animal experimentation and clinical experience prove this assumption. It has been shown that the myocardium of dogs poisoned with the diphtheria toxin, which have gone into failure, is relieved by the intravenous injection of glucose more quickly and satisfactorily than by any other means. Clinical experience also indicates that sugars give a better and quicker stimulus to an exhausted muscle than any other food or medication.

Fats should be eliminated as far as possible from the diet. Fats burn in the flame of the carbohydrates; therefore, in the cardiac patient who is overweight he should be forced to burn up his own fats and at the same time preserve the integrity of his body tissues by giving the appropriate amount of protein and carbohydrate. Arteriosclerosis and coronary sclerosis may be retarded if we paid more attention to the utilization of fats. Therefore, I repeat again, fats should be eliminated as far as possible from the diet, protein given in amounts just sufficient to insure against nitrogen loss, and carbohydrate in sufficient quantities to meet the caloric needs of the patient.

Attention must be given to the intake of minerals, vitamins and salts. To provide minerals, small quantities of the leafy vegetables and milk should be included in the diet. Orange juice and tomato juice provide sufficient vitamins. Salt should not be completely eliminated, except where there is edema, so that in the patient who has not gone into congestive failure the average amount of salt cooked in vegetables should be allowed, reducing the amounts of sodium bicarbonate and sodium chloride intake beyond that used in the kitchen.

The diet should never be bulky, and small frequent meals are to be preferred to three large or bulky meals. A simple dessert at the end of a meal gives a sense of fulness and satisfaction, which often enables a patient to rest contented with a smaller quantity of food than otherwise would be the case. Glucose taken between the meals in the form of "dextrettes" or glucose "suckers," such as sour balls, provides the needed energy and prevents the mental and physical exhaustion of which cardiac patients so frequently complain.

The diet in the patient with hypertensive heart disease, coronary sclerosis and angina pectoris should be the same as the keynote of his life: "moderation in all things." That is, prior to congestive failure, the diet should be sufficiently broad to include all the food elements, simple, well-balanced, and definitely limited in amount. The following foods should be avoided because they produce flatulency, are indigestible and capable of producing gastro-intestinal disturbances:

- |   |  |
|---|--|
| 1. Beans, especially dried.             | 14. Nuts.                                |
| 2. Cabbage.                             | 15. Onions.                              |
| 3. Cheese.                              | 16. Pastry.                              |
| 4. Corn.                                | 17. Pork.                                |
| 5. Corned beef.                         | 18. Potted meats.                        |
| 6. Condiments (mustard, tabasco, etc.). | 19. Preserved and pickled fish and meat. |
| 7. Cucumbers.                           | 20. Radishes.                            |
| 8. Duck.                                | 21. Raisins.                             |
| 9. Garlic.                              | 22. Rich desserts.                       |
| 10. Goose.                              | 23. Salty foods.                         |
| 11. Green and red peppers.              | 24. Sausages.                            |
| 12. Meat broths (especially soups).     | 25. Stews, sauces and gravies.           |
| 13. Melons.                             |  |

Following the general rules laid down above, and omitting the articles enumerated, three sample menus are given, which have been found of value to the cardiac patient who should limit his diet because of hypertensive heart disease, arteriosclerosis, coronary sclerosis or angina pectoris:

#### *Menu No. 1*

- Breakfast: Sliced orange or orange juice.  
 Wheatena with skimmed milk and sugar.  
 Poached eggs on toast (2).  
 Glass of skimmed milk.
- Lunch: Vegetable platter with poached egg.  
 Endive salad with cottage cheese.  
 Chocolate-flavored junket.  
 Melba toast.
- Dinner: Boiled lamb.  
 New peas.  
 Buttered cauliflower.  
 Stewed celery.  
 Lettuce and tomato salad, without dressing.  
 Bread and butter.  
 Sliced peaches.  
 Glass of buttermilk.

#### *Menu No. 2*

- Breakfast: Sliced pineapple (canned or fresh).  
 Oatmeal with skimmed milk and sugar.  
 Soft boiled eggs (2).  
 Toast and butter.  
 Skimmed milk.

Lunch: Split pea soup (without meat stock).  
Spinach with poached egg.  
Sliced bananas.  
Bread and butter.

Dinner: Stewed chicken.  
String beans.  
Boiled rice.  
Carrots, buttered.  
Tomato stuffed with cottage cheese.  
Bread and butter.  
Fresh grapes or strawberries.  
Glass of buttermilk.

*Menu No. 3*

Breakfast: Stewed prunes or apricots.  
Cream of wheat with skimmed milk and sugar.  
Poached eggs (2).  
Toast and butter.  
Skimmed milk.

Lunch: Vegetable soup (made without meat stock).  
Sliced cold boiled chicken.  
Creamed asparagus on toast.  
Stewed plums.  
Bread and butter.  
Glass of buttermilk.

Dinner: Broiled fresh haddock.  
Creamed cauliflower.  
Baked eggplant.  
String beans.  
Endive and orange salad with no dressing.  
Bread and butter.  
Jello, with fresh fruit.  
Glass of buttermilk.

NOTE: Tea, coffee and alcohol may be utilized in accordance with the individual case.

In the presence of edema due to myocardial failure, the best diet to be instituted is that formulated by Karell. This diet accomplishes the threefold purpose for which it is intended, namely, limitation of fluids, low sodium chloride intake, and restriction of caloric intake. At the end of one week with the subsiding of the edema, the modified Karell diet should be instituted, as follows:

*Standard, or Strict Karell Diet:*

Eight hundred cc. of milk is given daily, 200 cc. taken at each of the following feedings: 8 A. M., 12 noon, 4 P. M., and 8 P. M. This amount of milk will furnish

Protein . . . . .	26	Gm.
Carbohydrates . . . . .	40	Gm.
Fat . . . . .	32	Gm.
Sodium chloride . . . . .	1.6	Gm.
Water . . . . .	796	cc.
Total calories . . . . .	552	cc.

The above dietary is maintained for a period of one week, after which the modified diet is instituted, as follows:

*Modification of the Karell Diet:*

Eighth day:

Milk, 800 cc., in four feedings of 200 cc. each. This may be given at 7.30 A. M., 12 noon, 4.30 P. M., and 9 P. M. Or, it may be given at 8 A. M., 12 noon, 4 P. M., and 8 P. M.  
10.00 A. M.: 1 soft-cooked egg and 1 slice of toast.

Ninth day:

Milk, 800 cc., in four feedings (part of this may be made into junket, ice cream, and part in milk-soup if desired).  
10.00 A. M.: 1 egg and 1 slice of toast.  
12.30 P. M.: Milk-soup.  
4.30 P. M.: 200 cc. of milk, 1 slice of toast.  
8.00 or 9.00 P. M.: Milk, 200 cc.

Tenth to twelfth day:

Milk, 800 cc., 2 eggs, 2 slices of toast, 100 Gm. of cooked rice; one serving of asparagus, celery, cauliflower or carrots, prepared and distributed as described above.

Thirteenth to fifteenth day:

7.30 A. M.: 150 cc. of milk, 1 soft-cooked egg, 1 slice of toast, very little butter.

Noon: 1 poached egg on 1 slice of toast.  
100 Gm. of rice (well cooked and butter lightly); 150 cc. of milk: custard (made of 150 cc. of milk, 1 egg, <sup>1</sup>/<sub>2</sub> teaspoonful sugar).

4.30 P. M.: Soup (made of one serving of asparagus, celery or carrot, and puréed into 150 cc. of milk, seasoned with butter and dash of salt).

<sup>1</sup>/<sub>2</sub> = well-baked apple.

150 cc. of milk.

9.00 P. M.: 200 cc. of warm milk.

# DIET IN THE TREATMENT OF HEART DISEASE 1001

Sixteenth to eighteenth day:

7.30 A. M.: 50 Gm. of boiled rice with 50 cc. of milk.

1 egg, soft-cooked, 1 slice of toast, buttered.

150 cc. of milk.

Noon: One serving of asparagus, creamed with 50 cc. of milk and butter, served on one slice of toast, 30 Gm. of baked potato, with butter.

150 cc. of milk.

4.30 P. M.: 50 Gm. of boiled rice, 50 cc. of milk, 1 pat of butter.

1 baked apple with custard made of 1 egg and 50 cc. of milk.

150 cc. of milk.

9.00 P. M.: 150 cc. of warm milk.

Nineteenth to twenty-first day:

7.30 A. M.: 60 Gm. of cooked oatmeal.

1 soft-boiled egg.

1 slice of toast.

200 cc. of milk.

10 Gm. of butter.

Noon: 30 Gm. of baked potato; 1 pat of butter.

100 Gm. of boiled rice.

1 egg.

100 cc. of milk made into pudding of any type.

150 cc. of milk.

1 serving of stewed celery.

4.30 P. M.: 30 Gm. of baked potato, puréed with 100 cc. of milk.

1 pat of butter.

1 soft-cooked egg.

9.00 P. M.: 1 slice of toast.

1 baked apple.

150 cc. of milk.

In those few patients who have a definite milk intolerance, a diet similar to the following should be used to replace the strict Karel diet for the first seven days of treatment:

## Nonmilk—800 cc. Fluid Diet:

8.00 A. M.: 200 Gm. of barley gruel made with water, and seasoned with butter.

1 soft-cooked egg.

1 slice of dry toast.

Noon: 200 Gm. of potato purée, made with water and seasoned with butter.

Zwieback.

Baked egg.

4.00 P. M.: 200 Gm. of oatmeal gruel, made with water, and seasoned with butter.

1 slice of dry toast.

8.00 P. M.: 200 Gm. of potato purée, made with water and seasoned with butter.

Zwieback.

The Karell diet and its modifications are relatively severe, but the patient usually cooperates well when he notes the rapid disappearance of the edema. Cracked ice may be used to alleviate the thirst if the water is expectorated. Chewing of gum helps to avoid thirst, and the sucking of lemon sour balls not only relieves thirst, but also gives a readily available supply of glucose. I frequently place patients with recurring edema on the Karell diet one day or two days of each week, with much benefit. Where there is edema from other causes, such as orthostatic varicosities, postphlebitis, pregnancy, hepatic cirrhosis, or abdominal malignancy with ascites, benefit may be obtained from the use of the Karell diet.

In the acute cardiac accidents, such as acute coronary thrombosis, stab wounds of the heart, and contusions of the heart, the diet should be regulated to decrease the work demand of the heart. The Karell diet as outlined above may be used, or the diet advocated by Sir Thomas Lewis, as follows:

*800 Calorie Diet, to be Used for Five Days:*

8.30 A. M.: (a) Toast, 1 slice, with honey.

1 cup of tea, with two lumps of sugar.

or

(b) 1 raw egg in 6 ounces of milk.

1.30 P. M.: Minced chicken, 2 ounces.

Bread, 1½ ounces.

7.00 P. M.: (a) Custard, 5 ounces.

or

(b) Milk pudding, 4 ounces.

or

(c) Bread and milk (milk, 4 ounces; bread, 1 ounce, with a little sugar added).

Fluids should be tea or milk, and not to exceed 20 ounces, and to be taken between meals.

In conclusion, the character of the diet will not alter the course of the disease; but its well thought-out and considered

restriction will increase cardiac efficiency by relieving the heart of unnecessary effort, and will thus bring comfort to the patient and prolong his life. The rules worth following in the dietary regulation of the cardiac patient should be: (1) the maintenance of a normal weight and tissue nutrition, (2) a limited amount of protein, and (3) a liberal amount of carbohydrate.

## CLINIC OF DR. T. GRIER MILLER

GASTRO-INTESTINAL SECTION OF MEDICAL CLINIC, UNIVERSITY  
OF PENNSYLVANIA HOSPITAL

---

### THE ACUTE ABDOMEN AND THE GENERAL PRACTITIONER

I SHALL discuss a series of cases illustrative of the acute abdomen as encountered by the general practitioner. Surgeons usually talk about the acute abdomen, and properly so because it is one of their most puzzling problems and a problem which often they must solve without the help of various highly developed diagnostic procedures. In the presence of an acute suppurative appendicitis, an acute pancreatitis, a perforated duodenal ulcer or an ectopic pregnancy no time is available for elaborate roentgenologic studies, for chemical investigations of the blood, for a trial of some conservative medical regimen or even, not infrequently, for consultation with an internist. Consequently, the surgeons have become expert in recognizing, on clinical grounds alone, the cases in which operative therapy is indicated and those in which it is contraindicated. That decision is a most important one to make, and sometimes the only one that can be made, but unless, under the circumstances of each case, one has clearly in mind, as his ultimate goal, the determination of an exact diagnosis, he fails in his professional obligation.

Upon the general practitioner devolves the problem of selecting the cases that he shall have the surgeon see. Many of the cases with acute abdominal symptoms are not of a surgical nature and frequently, unless he believes them so to be, he is not justified in calling for surgical assistance: to do so under some circumstances may defeat the chief therapeutic indication, that of reassuring and putting at ease a distressed mind. Furthermore, to call a consultant, either internist or

surgeon, may impose an unnecessary financial burden or delay effective and prompt medical therapy.

It is necessary, therefore, that the general practitioner himself understand the acute abdomen and especially the disturbances that lead to it. This, in all fairness, the competent practitioner does understand, and often better than the average specially trained internist or surgeon because he has more frequent contact with it and because usually he is in possession of facts about the patient's past medical, family and social history, facts often that cannot be elicited by questions at a time of stress.

I shall attempt, therefore, to present the subject from a broader viewpoint than that of the person whose work is limited to any special field of medical endeavor. I shall not refer to the typical case of acute appendicitis, to the "frozen attitude" of the young man who falls on the street with the violent abdominal pain of a perforated duodenal ulcer or to the amenorrheic young woman who suddenly develops the phenomena of intraperitoneal hemorrhage, but rather to certain of the more confusing cases that I have encountered. In so doing I am selecting from my personal experience cases that originally at least presented a real problem in diagnosis and in some instances were correctly diagnosed only at operation or autopsy. A consideration of such cases should serve at least to develop in each of us a feeling of humility and caution in approaching every instance of the acute abdomen and always of erring, if one must do so, on the side of greatest safety for the patient, even if it involve a needless operation.

It may be objected that the cases I am about to present represent the rarer and more complicated instances of the acute abdomen and that they occur more frequently in the experience of the surgeon and medical consultant than of the general practitioner. To this I can reply only that such cases, at their onset, are encountered by the family physician and that, unless he appreciates their potentialities and acts on such a basis, the internist and surgeon will not see many of the cases when special therapy is still available.

Acute appendicitis, it must be admitted, is the most common and at the same time the most confusing of all the abdominal lesions that produce the acute abdomen. Every fourth

year medical student can diagnose the typical case, but one cannot practice medicine for long without appreciating that many cases present at first clinical phenomena that defy the classical picture: a misleading history, left-sided or upper abdominal pain or little pain anywhere, tenderness elsewhere than over McBurney's point, no gastric disturbance, no fever or increase of pulse rate, no leukocytosis. No one symptom or sign is diagnostic in all cases.

**Case I.**—I have today seen with one of our surgeons a patient, a man of forty, with a negative previous history, who along with his son developed abdominal pain two days ago and attributed it to oysters which they had eaten the preceding evening. The son recovered after an enema but the father continued to have generalized abdominal pain and marked distention, but no nausea or vomiting and free bowel action. Although he had generalized abdominal pain and tenderness, it was most marked in the left lower quadrant. One was tempted to think that he too had an acute enteritis, but he had a fever of  $99.4^{\circ}$  F., a pulse rate of 136 and rectal examination revealed tenderness in the midline of the pelvic basin. Operation disclosed that he had an acute appendiceal inflammation, the tip of the appendix being in the pelvis, with free fluid in the abdomen.

Such cases as this one are frequently encountered by the general practitioner and unless he bears constantly in mind the possibility of an atypical appendicitis, no matter what the character of the acute abdominal symptoms, an error in diagnosis or at least an unnecessary delay in diagnosis is likely to occur. Had we waited even for a few hours to secure typical localizing signs in this case the situation would have been much more serious and the chances of a fatal outcome greatly increased. No doubt this patient, like his son, did have an acute enteritis, sufficient to explain his loose stools, but, as a complication of that process, he developed an acute appendicitis. The latter might easily have been overlooked.

**Case II.**—Another patient, No. 2294, a woman of seventy-five, who had repeated gallstone attacks with jaundice and who was considered inoperable because of myocardial disease, de-

veloped in one attack localized tenderness and rigidity in the lower right quadrant of the abdomen with fever. Operation disclosed an appendiceal abscess. Her convalescence was satisfactory, but two years later she developed a watery diarrhea, nausea and vomiting without definite pain or distention. This was not diagnosed promptly but after three days the typical picture of intestinal obstruction developed and at operation it was found that a knuckle of bowel had been clamped off by an adhesive band in the appendiceal area. She died as a result.

In this case, although a previous appendectomy should have suggested the possibility of adhesive bands producing intestinal obstruction, I was misled by the previous history of gallstone attacks and by the diarrhea. More prompt hospitalization and consultation with a more experienced clinician would possibly have led to earlier recognition of the lesion and have saved the patient's life. In any event the experience has been a valuable one and has induced me on a number of occasions subsequently to suspect intestinal obstruction early and to act accordingly.

One not infrequently encounters a case in which the symptoms and signs seem to indicate an acute or subacute appendicitis, although at operation the appendix is normal. In the case detailed below it was only after a number of weeks following operation that a constricted and inflamed right ureter, believed to be the cause of the symptoms, was discovered.

**Case III.**—No. 4457, female, aged twenty-eight, the mother of three children, came in with a story of sharp pains in the lower right abdomen and slight fever for a week. Examination disclosed considerable tenderness deep in the appendiceal area, just above the brim of the pelvis. No superficial tenderness or rigidity was demonstrable. The leukocytes numbered 9100. A barium enema revealed a spastic cecum and tenderness about the base of a well-filled appendix. Urinalysis was negative and the basal metabolic rate was normal. Pelvic examination was reported as negative.

Although it was appreciated that the appendix might not be responsible, it was finally decided, after six days' observation, during which time the leukocytes had reached 10,600 and the temperature on a number of occasions 99.4° F., to ex-

plore the lower right abdomen. The appendix was not obviously diseased but it contained several fecaliths and a small hard nodule was found in its mesentery; it and the nodule were removed. The pelvic organs were normal to palpation and no other lesion was discovered. The appendix was found, on microscopic study, to be the seat of some chronic inflammation and the nodule to be due to chronic lymphadenitis.

Her pains persisted, grew more severe, she continued irregularly to be febrile, and finally a pelvic examination by another gynecologist revealed tenderness immediately over the lower right ureter. A urogram indicated some obstruction at that point and a cystoscopic examination showed evidence of a right-sided ureteritis. The introduction of a ureteral catheter reproduced the characteristic pain.

The diagnostic error made in this instance is perhaps excusable, especially in view of the reported negative pelvic examination and the negative urinalysis, but it serves to illustrate the care that should be exercised in the study of each case before operative interference. The subsequent course of the case has been such as to suggest that even the diagnosis of ureteritis may have been unjustified; treatment for that lesion led only to an increase of symptoms and cure was not obtained until after a prolonged course of psychotherapy. The latter incidentally involved the rationalization of many psychic traumas suffered in childhood. It is this aspect of a case that is often better understood by the family physician than by the so-called "specialist."

An acute cholecystic attack, although usually easily diagnosed, may also present clinical phenomena that defy prompt analysis.

**Case IV.**—No. 3458, male, a surgeon, fifty-two years of age, had suffered repeated attacks diagnosed left renal colic and after a fall on a golf course had developed severe epigastric pain with tenderness over the ensiform process. Soon the pain shifted to the right back, he had difficulty in breathing, a temperature of 100.4° F. and a leukocytosis of 13,400, later 24,000. Although at that time he had, in addition, some pain and tenderness in the gallbladder area his right diaphragm was fixed, expansion of the right chest was restricted, breath

sounds were faint and râles were heard. A right basal pneumonia was suspected and operation was withheld. Then he developed moderate jaundice, had an indirect van den Bergh reading of 3.2 units and no signs of consolidation appeared. Although repeated roentgenologic studies indicated some mediastinal reaction and a questionable lesion at the right pulmonary base, these cleared up satisfactorily and a Graham-Cole roentgenologic study showed no gallbladder shadow. The fact that his primary lesion on that occasion was an acute cholecystitis is indicated by the fact that two years later he had a similar attack, again with widening of the mediastinal shadow and fluid in the right pleural cavity (demonstrated by paracentesis). In spite of the signs of chest disease his abdomen was then explored by Dr. E. L. Eliason who found a perforated gallbladder containing stones and a subdiaphragmatic abscess. Following drainage of the gallbladder and the abscess he made a good recovery, but four months later reoperation was necessary for a common duct stone; at the same time the gallbladder was removed. He has had no symptoms during the three years that have elapsed since that time.

This case illustrates how a complication may obscure the symptoms and signs of the primary and more important lesion. Undoubtedly in his original attack this patient had an acute suppurative gallbladder superimposed upon a chronic calculous cholecystitis, later with extension of the inflammation up over the liver and through the diaphragm and finally a nonsuppurative mediastinitis. Whether or not operative interference at the time of the original attack was indicated is open to question, but the case serves to illustrate an acute abdomen due to a complicated situation, one that defies the best efforts of the internist and the surgeon as well as the general practitioner.

The value of roentgenologic study of the gallbladder is emphasized in the following case, one in which the original diagnosis was correct but in which subsequent events, with the exception of the Graham-Cole test, seemed to disprove that diagnosis.

**Case V.**—No. 4628, male, aged thirty-nine, with a previously negative history, developed during the night a severe pain in the right upper quadrant of the abdomen. When I

saw him a few hours later, marked tenderness over the gallbladder area was observed and the location and severity of the pain led to a diagnosis of cholelithiasis and morphine was administered. During the next five days he had several recurrences of the painful attack and became jaundiced. Finally he had an attack in which the gallbladder could be easily palpated, but the tender mass and the pain disappeared after morphine. Subsequently his symptoms disappeared completely and it was then learned that his friends had noted some jaundice for several weeks before his original attack. That item of history, together with the sudden enlargement and quick disappearance of the gallbladder mass, led to conservative therapy, and after about two weeks all the symptoms and signs of disease had disappeared.

At that stage it was suspected that the original diagnosis of gallstones was in error and that he had had only an acute catarrhal jaundice with common duct obstruction. Biliary drainage showed good gallbladder concentration but a roentgenological study revealed a single large gallstone (a negative shadow). Because of that observation, and in spite of his history of painless jaundice preceding the painful attacks, operation by Dr. E. L. Eliason disclosed a single stone embedded in the wall of the ampulla of the gallbladder. He has been entirely well since the operation.

This case illustrates the importance of making every possible study in order to arrive at a correct diagnosis. Although the history, the physical signs and the biliary drainage results seemed consistent with the diagnosis of acute catarrhal jaundice, and one might have gone no further in his study of the case because for the time being the patient was symptom-free, the roentgenologic investigation gave immediately a positive diagnosis of cholelithiasis and indicated surgical therapy. I believe that every case of so-called "acute catarrhal jaundice" should subsequently have a biliary drainage and a cholecystogram. Many of these cases eventually come to operation for gallstones.

As an illustration of an acute abdomen, at least in its demand for prompt and effective therapy, I now cite a case of urinary bladder obstruction that was at first looked upon as an instance of indigestion on a cardiac basis.

**Case VI.**—No. 903, male, aged seventy-five, who had been under my observation twelve years previously because of nervous symptoms and some frequency of urination, consulted me again in February, 1934, with the following story. For several months he had been having cardiac symptoms and he had finally, two weeks previously, gone to Atlantic City, under a physician's orders, for a rest. Immediately he had developed marked nausea and vomiting, could not take food or even water without vomiting. None of the measures for the control of his indigestion prescribed by a local physician had been of any benefit.

He looked worn and distressed, was pallid and very restless and talked hesitatingly and with difficulty in finding the proper words. I noted an ammoniacal odor on his breath and found his lower abdomen distended and dull to percussion. He voided some urine but without effect on the cystic lower abdominal mass. The urine was negative but for a low specific gravity (1.008). Prostate was only moderately enlarged. At the same time, because of the general state of the patient and the large mass, suggestive of a markedly distended bladder, I took blood for the determination of its urea nitrogen content. That proved to be 64 mg. per cent.

He was immediately hospitalized and his urinary bladder decompressed. Two days later his urea nitrogen concentration was still 63 mg. per cent, but within two weeks this figure was practically normal and Dr. Alexander Randall then was able to remove a part of the median lobe of his prostate by the electric method. He made a good convalescence and by May, 1934, his urea nitrogen was 14 mg. per cent. He has had no further cardiac, digestive or urinary tract symptoms.

Coronary thrombosis, especially of the posterior branch, may present a clinical picture suggestive of an acute digestive disturbance. I have had the following distressing experience.

**Case VII.**—No. 1030, female, aged forty-five, for about five years, following the cessation of menstruation, had had, in addition to hot flushes and sweats, a distinct tendency to adiposity, a moderate increase in blood pressure and attacks

of urticaria. In 1934 she developed pain in the feet on walking, which special tests by Dr. Lewis H. Hitzrot seemed to indicate were on a basis of vascular spasm; no organic vascular lesions could be demonstrated. Soon her blood pressure had reached 180/120, but clinical examination of the heart and urinalyses were negative. Blood studies were negative.

One evening, while sitting quietly at her home, she developed suddenly epigastric pain, which her husband, a physician, believed to be on a digestive basis. She took some codeine and the next morning felt well except for a feeling of fulness in the abdomen. She had a colon irrigation in the afternoon and felt relieved, though the abdomen was still somewhat distended and she was slightly nauseated. She was able to go out for a walk that afternoon, but soon after returning home she developed a violent pain beneath the sternum with radiation into the lower jaws. Then, for the first time, a coronary lesion was suspected and electrocardiographic study indicated that she had a posterior wall infarct. Subsequently she developed pulmonary and cerebral infarctions from which she died.

This case is also interesting in that the patient had previously demonstrable evidence of peripheral vascular disease and that such disease came on with the onset of her menopause and was associated with vascular hypertension. Thus it suggests a coronary rather than a myocardial explanation for some of the cardiac symptoms of menopausal hypertension. In any event this case serves to emphasize what is already well known, that coronary occlusion may mimic the symptoms of a digestive disorder.

Rupture of the thoracic aorta is an unusual occurrence, but, in addition to the case which I shall now report, I have seen the autopsy specimens of a similar case which was presented in a clinical-pathologic seminar at the Presbyterian Hospital in New York. Both cases had a history indicative of an upper abdominal catastrophe, such as an acute pancreatitis or a ruptured duodenal ulcer.

**Case VIII.**—No. 957, male, aged fifty-five, had been under my general observation for fourteen years. He had had headaches all his life and for more than twenty years he had had

digestive symptoms, but all studies had failed to reveal any organic disease. Blood pressure, urinalysis, blood counts and Wassermann test had always been negative.

At 11.20 A. M. on the morning of June 5, 1929, while swimming in an indoor pool, he developed a sharp pain in the epigastrium. He was able to get out of the pool, dress himself and come to my office. I found him ashen gray in color and obviously suffering greatly. The pain by this time was both epigastric and lumbosacral. The upper recti seemed resistant, but there was no boardlike rigidity. The upper abdomen was tender, especially on the right side. A perforated ulcer or an acute pancreatitis was immediately suspected and he was promptly taken to the University Hospital. While undressing he developed a sudden exacerbation of the pain and fifteen minutes later another such attack. His leukocytes numbered 20,400. He was given morphine and scopolamine. The next morning his temperature was but 99° F. and his pulse rate 88, but he had 21,000 leukocytes. Dr. John B. Deaver thought he had an acute pancreatitis with hemorrhage into that organ. Two hours later he died suddenly and an autopsy revealed an unsuspected rupture of the lower thoracic aorta.

As representative of the abdominal crises of *tabes dorsalis*, I present a case that fortunately was recognized and that did not undergo the various operative procedures that are so frequently reported in that disease. It is only fair to say, however, that in this instance, had the diagnosis of *tabes* not been made in advance and the typical physical signs sought for, operative therapy might have been considered for the severe abdominal pains.

**Case IX.**—No. 3911, male, fifty-eight years of age, complained of irregular seizures of gnawing abdominal pain, chiefly in the epigastrium. In addition he had regularly a sense of heaviness in the epigastrium after meals and much flatulence. Extensive studies of the digestive tract, including complete roentgenologic investigation, were negative but for spasm of the colon in the splenic area.

Careful inquiry into his history then disclosed that at the age of thirty he had a suspicious primary syphilitic lesion and on neurologic investigation it was found that he had Argyll

Robertson pupils, diminished patellar and Achilles reflexes and possible ptosis of the eyelids. On the basis of these observations a diagnosis of tabes was made and intensive antiluetic therapy after a few years brought about a complete disappearance of the abdominal attacks.

Finally, I wish briefly to outline the data obtained in our wards on a patient who was proved eventually to have polycystic kidney disease. This is an unusual lesion to associate with an acute abdomen, but the superimposed renal infection, a pyelonephritis, which accounted for the patient's original symptoms, not infrequently, like pyelitis, causes acute abdominal distress. The case should emphasize the importance regularly of making a careful microscopic study of the urine, as well as a general physical examination, in every case of the acute abdomen.

**Case X.**—No. 35-21807, a married woman of forty-nine years, was admitted to one of our surgical wards on December 29, 1935, for what was believed by her family physician to be an attack of acute appendicitis. Two days previously she had developed a sharp pain in the lower right quadrant of the abdomen with associated pain in the right flank and chilly sensations. Because of marked tenderness in the costovertebral angles, as well as in the right upper and lower quadrants of the abdomen, the presence of a mass in the right upper abdomen, a temperature of 104° F. and much pus in the urine, the diagnosis of appendicitis was considered inadequate and some renal lesion was suspected. A flat roentgenologic film showed shadows in both kidney areas that suggested the possibility of polycystic kidney disease. She was transferred to one of our wards two days after admission and further studies confirmed that diagnosis. Cystoscopic investigation revealed cystitis and evidence of infection in both kidneys. A pyelogram showed enlarged kidney pelves, probably due to polycystic disease; a urogram confirmed this. Urea nitrogen concentration was 19 mg. per cent but phthalein elimination for a two-hour period was only 25 per cent. Her fever subsided and leukocytes dropped to normal, but she still showed pyuria on discharge January 26, 1936.

She was readmitted on August 31, 1936, after another at-

tack of right upper quadrant pain with bloody urine. Masses were then easily palpable in the kidney areas, the urea nitrogen concentration was 118 mg. per cent and the phthalein output was only 5 per cent. Uremia led to her death on September 15 and autopsy confirmed the diagnosis of polycystic kidney disease with acute pyelonephritis.

These references to specific cases by no means cover the lesions responsible for the acute abdomen. One has only to think of acute pancreatitis, of ruptured duodenal or gastric ulcer, of traumatic lesions, such as a rupture of the liver or spleen, of certain intoxications, of mesenteric thrombosis, of brain tumor, of migraine, of acute enterocolitis, of intercostal neuralgia, so-called, and, especially in children, of rheumatism, to realize that I have barely approached the subject. Every physician, be he general practitioner, internist or surgeon, must constantly have all of these possible lesions in mind when he encounters the acute abdomen.

## CLINIC OF DR. H. L. BOCKUS

GRADUATE HOSPITAL, UNIVERSITY OF PENNSYLVANIA

### THE IRRITABLE COLON: DIAGNOSIS AND TREATMENT

It is possible to segregate from the functional disorders of the colon a group of cases having in common a disturbance of the neuromuscular mechanism of the bowel for which there is no organic cause, such as colonic disease, parasites, anomalies or disease outside the colon causing reflex symptoms. Formerly many of these cases were designated as spastic colon, mucous colitis and chronic colonospasm. These appellations are gradually being discarded. A diagnosis of colitis should be reserved for cases of primary inflammation of the colon. The neuromuscular disturbances are not always associated with increased tonus and shortening of the circular or longitudinal muscle fibers. Some instances of extreme atony must be included in the same general category of the neurogenic colonopathies. Consequently, the terms "irritable colon" (Jordan and Kiefer) and "unstable colon" (Kantor) are now being applied to this group of cases. Hurst has recently discussed the functional colonic disturbances under the title of the "unhappy colon." Possibly a clearer concept of the syndrome would be had if the whole group was designated as follows (Bockus and Willard):

#### COLONIC NEUROSES—IRRITABLE AND UNSTABLE COLON

1. Motor neurosis—disturbances of tone or peristalsis—including colonospasm, atony and nervous or emotional diarrhea.
2. Secretory neurosis—increase (mucous colitis) or diminution in the secretion of the mucous glands.
3. Mixed neurosis—characterized by dysfunction of both the motor and secretory mechanism. This classification serves to emphasize the protean character of the functional dis-

turbances of the colon, all of which depend upon an underlying lack of balance of the vegetative nervous system. Motor disturbances are more commonly encountered clinically. The mixed neuroses are next in frequency. The pure secretory disturbances are quite uncommon in the absence of concomitant spastic phenomena. The same patient may manifest any type of secretory or motor dysfunction at different times so that for clinical purposes a diagnosis of colonic neurosis, irritable or unstable colon is sufficiently accurate.

**Etiology.**—We cannot discuss in detail the various etiologic factors which can account for this syndrome. Any mechanism capable of influencing the vegetative nerve supply to the large bowel may be responsible. No one questions the importance of the psyche in many instances. A colonic neurosis is a civilization disorder. It is more commonly encountered in the more emotional races (Jews and Latins) and among emotional and so-called “temperamental stock.” Females are more frequently affected. Emotional or nervous stress and strain is often provocative of attacks in susceptible people. Although the psychic factor is often dominant, it is by no means universal. The underlying autonomic disturbance probably depends upon dysfunction of one or several units of the endocrine system. Both hyper- and hypofunction of the thyroid are frequently accompanied by “irritable” colon symptoms. Symptoms are commonly related to menstrual function. Ovarian dysfunction is noted in a high percentage of female patients with a colonic neurosis. There can be no question of the influence exerted by the pituitary, adrenals and the internal secretion of the pancreas on the abdominal sympathetic system. A fertile field for investigation remains to be explored in this realm of endocrinology. Allergic states unquestionably account for the initiation of irritable colon symptoms in many instances so that a great many factors, both exogenous and endogenous, must be considered in a careful survey on patients considered to be allergic. Many writers consider primary infection of the colon and simple constipation (habit type) as causes for the development of symptoms of colonic irritability. Cases of this type should be excluded from the “irritable colon” family and given their true designation of catarrhal colitis or simple constipation or dyschesia.

As a rule symptoms of colonic irritability do not occur in simple constipation until laxatives, cathartics, enemas or colon irrigations have been used for a long period of time. These symptoms depend upon an actual colitis and will disappear upon withdrawal of the offending agent unless the constipation was primarily due to an underlying neuromuscular dysfunction.

**Diagnosis.**—Symptoms attributed to the colonic neuroses comprise from 15 to 45 per cent of visits to internists interested in digestive tract disorders. Surely, this high incidence constitutes in itself a sufficient plea for a thorough understanding of the condition by every internist and surgeon. A long history of recurring bouts of abdominal discomfort related to or associated with irregular bowel habit constitutes the presenting complaint in most instances. The pain may be anywhere in the abdomen but is more often experienced in the lower quadrants, usually the lower left. It may be severe or mild but is commonly crampy and described as a feeling of "gas." Constipation or diarrhea may be present but at any rate the abdominal discomfort is often influenced by the act of defecation or expulsion of gas. A diagnosis of the "functional colon" must be made by exclusion. First of all, one must eliminate organic colonic disease, such as neoplasm, diverticulosis, bowel obstruction, dysentery, tuberculosis, ulcerative colitis or polyposis. A diagnosis of organic disease of the colon can usually be made without difficulty after physical examination, fecal analysis, proctosigmoidoscopy, rectal and roentgenologic examinations. If organic disease of the colon can be reasonably ruled out, consideration must be given to extracolonic diseases, which can reflexly disturb the function of the colon. Appendicitis, renal calculus, pyelitis, and pelvic inflammatory disease are common offenders but are rarely active over such long periods as the colonic neuroses. They are, of course, more prone to show signs of sepsis, fever and leukocytosis. However, in some cases the diagnosis will not be easy. A previous attack of appendicitis or pelvic inflammatory disease is at times followed by mechanical disturbances, which may induce symptoms quite similar to a true colonic neurosis. Nevertheless, entirely too many operations have been performed for the relief of irritable colon symptoms with the mis-

taken diagnosis of recurring appendicitis or some other acute intra-abdominal lesion. In the absence of symptoms and signs of acute appendicitis, laparotomy should always be postponed until a thorough investigation has been carried out and a trial on "irritable colon" management instituted. Recurring spells of diarrhea unassociated with the passage of pus or blood in the stools is frequently due to a "colonic neurosis," particularly if abdominal crampy pain is present. However, achlorhydria must always be considered, as it is a not uncommon finding in patients with the irritable colon. Symptoms of colonic dysfunction are often influenced by this gastrogenous factor and the administration of hydrochloric acid may bring about relief of the diarrhea and improvement in pain. A true gastrogenous achlorhydric diarrhea in the absence of an irritable colon rarely gives rise to abdominal pain preceding evacuation. Many other abdominal lesions and certain constitutional maladies, such as sprue and tuberculosis as well as lesions of the central nervous system may initiate an irritable colon syndrome. Almost any type of deficiency disorder may give rise to diarrhea or other manifestations of colonic dysfunction, which cannot always be differentiated from a true colonic neurosis. Indeed one occasionally encounters patients with a deficiency disorder induced by dietary restrictions imposed for the relief of colonic symptoms.

Granting the exclusion of all extraneous causes of colonic dysfunction, what are the criteria for the diagnosis of a true colonic neurosis? The *history* of the relationship of the abdominal discomfort to bowel evacuation in an individual with a disturbance of bowel habit is of paramount importance. The linking up of symptoms to evidence of psychic or vegetative imbalance is equally significant. Clinical evidence of an endocrine disturbance or allergy lends further support to the possibility of an irritable colon. The *physical examination* may reveal nothing abnormal with the exception of tenderness over the pelvic colon which may be stiff and narrow or lumpy due to scybala. I cannot refrain from sounding a word of warning concerning the possibility of a parietal abdominal neuralgia (Carnett) to account for pain of undetermined origin in one of the abdominal quadrants. One should hesitate about attributing pain which is constant for weeks or months to an irritable

colon even though a diagnosis of irritable colon is tenable for other reasons. Abdominal neuralgia and irritable colon commonly coexist in the same individual but treatment for the latter cannot be expected to influence the neuralgic type of pain. In my experience the superficial tenderness which is elicited by pinching a fold of skin and fat or making firm pressure on the abdominal wall made tense by straining is commonly due to postural strain, spinal curvature or spinal arthritis. This type of tenderness is frequent in patients complaining of a constant pain not influenced by bowel evacuation. Tenderness dependent upon colonic spasm is usually deep and elicited only when pressure is made directly over the colon (see Case II). The third aid in the diagnosis of the irritable colon is the *analysis of the feces*, too frequently neglected. The shape of the stool before or during attacks is often abnormal. It may be pencil shaped, flattened or scybalous. Clear, so-called "neurogenic mucus" may be seen on the outside of the movement in some cases. The stools may be mushy or even liquid for long or short periods of time. In a negative way the absence of gross or occult blood, pus and parasites is of importance. The *sigmoidoscope* is of great help in the diagnosis. Primarily it will assist in excluding the organic colitides and new growths, both of which commonly occur in the lower 10 inches of the bowel. In patients with the irritable colon, great difficulty is often experienced when the instrument is being introduced into the sigmoid. Severe pain in the lower abdomen is not infrequently due to the marked spasm of the musculature of the sigmoid. The ability to reproduce pain similar to the patient's chief complaint by manipulation of the instrument or the introduction of air into the bowel is a rather common experience. A clear, "non-inflammatory" type of mucus may be encountered within the lumen of the bowel.

A properly executed *roentgenologic study* of the colon is essential. An ordinary opaque enema will suffice in many cases but may need to be supplemented in others by a double contrast barium and air enema or by a progress meal study. First consideration must be given to the ruling out of organic disease, particularly in that portion beyond the reach of the sigmoidoscope. The opaque enema should be introduced very slowly

at body temperature and its rate of flow into the colon noted. In some cases of irritable colon the barium will be observed to pass up the lumen of the colon very rapidly. This is an indication of extreme irritability. The introduction of barium, even when given slowly, may produce subjective pain quite similar to the abdominal pain for which a physician's aid is sought. The silhouette of the filled colon will obviously be quite variable in different cases, and not infrequently change

Fig. 59.—Combining the features of extreme narrowing of the left colon and zonal span. Marked contractions are noted in 3 areas, the sigmoid, the midtransverse colon and the cecum. The symptoms were severe and closely simulated, at times, acute appendicitis.

considerably from time to time in the same patient. It can be markedly changed by the addition of more barium or by the expulsion of some of the barium contents into the ileum. Abnormal narrowing of some colonic segment, more particularly the left, is a common type of abnormality. Another less frequent finding is segmentive or zonal spasm. It is more often seen in the sigmoid and descending colon (Fig. 59). A deep-cutting contracture of spastic nature confined to the proximal

ascending colon is usually dependent upon some type of local disease in the vicinity, such as tuberculosis, malignancy, appendicitis or other mucosal disease. A considerable number of irritable colon cases show the fine, shallow, irregularly arranged, saw-tooth type of colonic margin described by Spriggs and Marxer as prediverticulosis (Figs. 62, 63). Haustral markings may be grossly exaggerated, markedly irregular or totally absent and all variations in between will be encountered. A markedly dilated atonic bowel may at times depend upon a primary neuromuscular disturbance or it may develop secondary to long-standing dyschesia. In extreme irritability of the colon I have seen occasionally all of the classical and so-called "pathognomonic signs" of ulcerative colitis, namely, shortening, narrowing and lack of haustrations (Fig. 60). This appearance is rarely permanent unless due to an actual inflammation of the colon. If due to irritability the same colon may show deep-cutting haustral contractions on the twenty-four- or forty-eight-hour mouth-meal films, indicating that the smooth appearance on the enema film is not the result of actual disease of the bowel wall.

**Treatment.**—The large group of patients with subjective complaints dependent upon colonic irritability constitute a real problem in office practice. Are the symptoms due to organic disease in the colon? An individual with a long history of irritable colon may, of course, develop an organic lesion. Ruling out this annoying possibility, isn't it remotely possible that there is a chronic pelvic inflammation, a mechanical appendix, a renal calculus or pyelitis? Mature judgment in the selection of diagnostic procedures and a period of observation is often essential before a definite decision can be made. What of the thyroid? Is the fatigue syndrome due to hypothyroidism? Does the extreme nervousness depend upon a not very obvious thyrotoxicosis? Does the menstrual irregularity depend upon a pituitary, ovarian or adrenal abnormality? Some cases will require complete surveys of this type before one can be sure. Was the previous dermatitis on an allergic basis and can one positively rule out food allergy? Possibly a detailed study of this kind may be necessary. How significant is the nervous factor? Why is the patient always symptom-free when away from home? Is the disturbing influence at home

or in business? Does an anxiety neurosis or hysteroid disposition play a part? Are the symptoms bona fide, or is the patient basically hypersensitive, or may the syndrome be entirely explained on a "substitution basis?" Should one institute a psychiatric study now or would it be wise to go slowly with this type of questioning for the present? Does tobacco play a part? Is bridge a factor, and so on ad infinitum? Here is an ailment in which equal attention must be paid to the psychic and the somatic sides. Here one needs the training of a well-rounded internist and psychiatrist combined with the sage wisdom of a philosopher. Those who approach this problem with a sense of security and smugness, using only stereotyped methods, are doomed to frequent failures. It is quite impossible to discuss the management of cases of this type in detail without writing a lengthy monograph. Briefly, the treatment may be considered under two headings: (1) measures directed toward the alleviation or cure of the underlying cause, and (2) local measures directed toward the colon.

1. *General Measures.*—Focusing primary attention on the colon is obviously treating only a symptom in most instances. The therapy of real value is that directed toward the cause of the vegetative nervous system abnormality if it can be ascertained. The psychic factor will need attention in many. This may mean a very definite readjustment based upon psychiatric study. Environmental changes may be necessary. Causes for outbursts of emotion, periods of depression and prolonged grief must be sought and alleviated in so far as possible. Removal to a hospital may temporarily ameliorate an imminent or immediate crisis and allow time for outlining a more deliberate and lasting plan. A holiday from home and business is frequently beneficial. Therapy must include avoidance of those factors which have been known to precipitate attacks. This may include public speaking, bridge playing, excessive smoking or overwork. Hygienic faults should be corrected if possible. Sufficient sleep, a mid-day rest, moderate exercise and diversion, and regular hours of eating in pleasant surroundings may prove beneficial. It is usually wise after explaining the nature of the illness to write out a specific program to be followed. Sedatives may be necessary to insure adequate sleep and al-

leviate mental anxiety. Specific measures may be indicated to correct an underlying abnormality of the endocrine system or an allergic state. Occasionally it seems advisable to remove surgically or treat medically a pathologic focus in some other abdominal organ, although, in my experience, chronic gall-bladder disease and so-called "chronic appendicitis" are rarely the cause of an irritable colon syndrome. If achlorhydria is present, dilute hydrochloric acid should be tried even in the absence of diarrhea, as it may improve the colonic instability. The healing of a duodenal ulcer will often bring about a cessation of colonic symptoms when the two conditions coexist.

2. *Local Measures.*—The diet should be bland during attacks and possibly free from coarse cellulose fiber at all times. Ice cold or very hot food and liquid are not advisable. The diet should be adequate in calories and balanced to contain all the essentials for normal nutrition. A carefully taken dietary history will often reveal inadequacies or indiscretions which can be corrected. Many of these patients become food faddists after long suffering and failure to obtain benefit from regular physicians and require intelligent handling to be convinced of the rationale of the diet prescribed. If the capacity of the colon is large and obstinate constipation is present, nonirritating residue in the form of agar, kaolin, or one of the mucilaginous preparations, such as Mucilose, Metamucil or Konsyl, should be used in sufficient quantity to insure the passage of stools of adequate size. Those who pass dry, fragmented stools should take mineral oil. The disagreeable leaking of the oil so commonly present in cases of spastic colon can be prevented by the addition of adequate quantities of one of the above substances. All irritating laxatives should be avoided. If constipation is marked, magnesium oxide may be used in sufficient quantities to overcome it in most instances. The dose can be gradually reduced as bowel function improves. One of the best drugs in these cases is belladonna. It may be prescribed as the extract with magnesium oxide and kaolin in powder form. One of the favorite prescriptions of the author is: Ext. bell. gr.  $\frac{1}{4}$ , calcined magnesia gr. 10, calcium lactate and kaolin 5̄ā dr.  $\frac{1}{2}$  three times daily before meals. Enemas and irrigations are not used except in emergency during the beginning of the regimen or during an attack in the manner

described below. We feel that the routine use of solutions injected into the bowel only tends to irritate the bowel and disturb its normal rhythm. For relief of pain which may be very severe during the acute exacerbation, principal reliance should be placed upon antispasmodics and sedatives. Atropine with bromides and phenobarbital is an excellent combination. Opiates should be avoided because of the chronicity of the condition and danger of habit. Better results will be obtained if the patient is confined to bed until the attack has entirely subsided. Hot, moist applications or a warm tub bath often help to alleviate the pain. A warm injection of several ounces of olive oil, cotton seed oil or a solution of barium sulfate may bring about rapid relief. A course of calcium and parathyroid seems of benefit in assisting to control a particularly severe attack in some patients. Dorst, Mateer, Berger and others have reported increased skin sensitivity to bowel organisms in some cases of irritable colon. Autogenous and stock vaccines of colon organisms have been found beneficial by these observers. Other methods of desensitization, such as the administration of sodium ricinoleate, 5 to 10 grains twice or three times daily, have been recommended by Dorst. The author has had little experience with vaccine therapy but has used sodium ricinoleate in those cases with allergic manifestations with some benefit. I doubt if this type of management strikes at the root of the trouble except in occasional cases and consequently do not recommend these measures routinely. The use of so-called "specific methods" of treatment for conditions which are probably not primarily bacterial does not seem rational.

**Case I. Illustrating Severe Colonospasm in a Patient with Obesity, Possibly of Pituitary Origin.**—M. P., a single female Jewess, twenty-seven years of age, appeared December 13, 1936, complaining of attacks of excruciating pain in the lower left abdominal quadrant of several days' duration, associated with frequency of urination and desire for frequent defecation. The attacks were of such intensity and frequency that the patient had spent a great part of her time in bed since the onset in November, 1935. She had been slightly constipated previous to the onset and often resorted

to mineral oil. Enemas, prescribed for the relief of pain, were discontinued because they accentuated the pain. Excessive fatigue and dizziness were subsidiary complaints.

The patient and her family were extremely apprehensive and nervous. She weighed 14½ pounds at birth and had been obese always. Menses started at the age of eleven years and occurred regularly thereafter, lasting six or seven days and accompanied by severe cramps. Since the onset of the present

Fig. 60 Case I Showing extreme narrowing and lack of haustrations. This can now be differentiated roentgenologically from chronic ulcerative colitis.

illness the lower left quadrant pain was always worse at the onset of menstruation.

The physical survey was negative except for masculine hair distribution, tachycardia and obesity; weight 170 pounds, height 60½ inches. The previous "best weight" was 240 pounds, four years previously. Weight loss resulted from a strenuous reducing diet, instituted in March, 1936, which seemed to aggravate the chief complaint. The blood pressure was 124 systolic and 78 diastolic. Examination of the feces,

urine and blood revealed nothing abnormal. The basal metabolic rate was minus 9. Venepuncture was refused so that sugar tolerance and blood cholesterol determinations have not been performed to date. The sigmoidoscope could not be passed beyond the rectum because of feces, spasm and apprehension. A small hemorrhoid was found. The pelvic colon was felt as a fountain-pen-sized tube which was exceedingly tender and this tenderness corresponded to the location of the chief complaint. Barium enema study failed to reveal diverticulosis or other organic colonic disease. The left colon maintained a narrow contracted lumen throughout the period of observation (chronic continuous colonospasm). Barium entered the colon at low pressure very rapidly and caused considerable discomfort. All semblance of normal haustral markings were absent. It would have been impossible to exclude advanced ulcerative colitis from the barium study alone (Fig. 60).

The patient was placed on a regimen including a bland, high vitamin, well-balanced diet, psychotherapy, small olive oil instillations into the rectum, heat to the abdomen, sedation, antispasmodics and calcium. Unfortunately she developed an acute hemorrhoidal crisis, requiring surgical treatment, which interrupted the irritable colon regimen. Since then she has improved somewhat. Endocrine therapy has been withheld up to the present.

The case is cited to illustrate the advanced state of ill health and suffering which may be anticipated in some cases. The extreme hypertonicity and narrowing of the left colon, noted in this case, is not infrequently associated with symptoms of great severity and frequency. The underlying vegetative instability is probably of pituitary origin conditioned by an anxiety state, the exact nature of which remains obscure.

**Case II. Illustrating the Irritable Colon Syndrome in Association with an Anxiety Neurosis, Achlorhydria and Abdominal Parietal Neuralgia for which Two Laparotomies were Performed without Relief.**—A. B., a married Italian female, was admitted to the Graduate Hospital, July 17, 1935, complaining of constant pain in the left midabdomen and alternating attacks of constipation and diarrhea with the

passage of mucus in the stools. There had been one pregnancy in 1930 which was followed by the first attack of diarrhea.

The past medical history is illuminating and will be given in some detail as it is typical of many patients of this type.

January, 1932.—Onset with postprandial, epigastric distress, nausea and vomiting. Treated for intestinal "flu"; no relief. Admitted to a hospital on the service of a gynecologist for two weeks. Released on diet and medication; no relief. Onset of diarrhea and midabdominal pain; sent to another physician. Diagnosis: *dropped stomach*. Admitted to second hospital for three weeks. Diagnosis: *intestinal tuberculosis*. Pain now centered about lower right quadrant. Colonic irrigations started. Admitted to third hospital; signed release.

May, 1932.—Admitted to fourth hospital. *Appendectomy* performed; no relief. Remained in hospital eight weeks on sedatives. Constipation severe. Suppositories started; weight dropped from 116 to 88 pounds. After one month admitted to fifth hospital. Some insight into true nature of affairs resulted in regimen for weight gain combined with psychotherapy. Weight rose to 135 pounds; returned to work February, 1933; remained quite well until:

November, 1934.—Nausea and vomiting recurred; mucus first appeared in stools; pain in left midabdomen recurred. A narcotic medicine was prescribed; no relief without it. Narcotics discontinued after four weeks. Readmitted to fifth hospital for study and intravenous medication for radiculitis.

February, 1935.—Admitted to sixth hospital. Disease of *left kidney* and *ulcerative colitis* was suspected. Oil enemas prescribed. Narcotics hypodermically were resorted to frequently. "Mucous diarrhea" and fainting spells.

March, 1935.—Admitted to seventh hospital. Tentative diagnosis of intestinal tuberculosis made. Signed release. "Daily needles."

April, 1935.—Readmitted to fifth hospital for midabdominal pain. Operation for release of *abdominal adhesions*; no relief. "Incision open and draining for 4 weeks." Home three weeks in bed with sedatives; no relief.

June, 1935.—Consulted another physician in another city who diagnosed *mucous colitis*. Suppositories prescribed.

On arrival at the Graduate (her eighth hospital), she

weighed 108 pounds; had been eating copiously of roughage and seemed to be in acute pain. The physical examination was negative except for slight hypertension (144/88) and tenderness in the abdominal wall just to the left of the umbilicus. The spine films showed very early arthritic changes in the lower thoracic vertebrae and slight dorsolumbar lordosis. The temperature and blood count were normal. Analysis of urine and feces showed nothing of consequence. Fractional

Fig. 61.—Case II. Film shows no evidence of colonic irritability although bowel function had been abnormal for five years. The fluoroscopic findings were typical of irritable colon.

gastric analysis revealed an achlorhydria. Histamine, however, elicited an acid response—HCl 15 after forty-five minutes. Sigmoidoscopy—normal mucosa of the rectum and sigmoid. The barium enema revealed a long colon, which was noted by the fluoroscopist to be extremely irritable and spastic, although the film (Fig. 61) does not indicate much spasticity. The capacity of the colon was not reduced but the introduction of the barium caused marked discomfort. The late Dr. Clarence Patten examined the patient and diagnosed

an anxiety neurosis probably dependent upon marital difficulties. Dr. William Bates injected novocain locally into the tender area of the parietes and brought about immediate relief of the tenderness.

Treatment consisted of postural corrective exercises, a bland diet, belladonna, phenobarbital, charcoal, bismuth and kaolin; sodium ricinoleate, rectal instillations of olive oil if constipated, hydrochloric acid after meals and psychotherapy with an attempt at improving domestic relations. She responded satisfactorily. She was seen in March, 1936, symptom-free and four months' pregnant.

The failure to appreciate the frequency with which parietal abdominal neuralgia and unstable colon may give rise to recurring bouts of severe abdominal pain accounts for this patient's round of visits to innumerable physicians and 8 different hospitals. The diagnoses included dropped stomach, intestinal tuberculosis, ulcerative colitis, appendicitis, abdominal adhesions and disease of the left kidney. The economic loss entailed by her illness is appalling. The opium habit was in the offing on two different occasions. It seemed likely that the anxiety neurosis may have been primary. The tendency to diarrhea was considerably increased by the achlorhydria, as she responded quickly to hydrochloric acid. However, the alternating constipation and diarrhea with excessive mucous discharge undoubtedly resulted from neuromuscular instability of the colon; the emotional factor being of paramount etiologic significance. The constant left abdominal pain was probably due to a localized parietal abdominal neuralgia, immediately the result of postural strain but conditioned undoubtedly by the underlying nervous hypersensitivity.

**Case III. Illustrating the Coexistence of an Irritable Colon (Prediverticulosis) and Duodenal Ulcer.**—A. D., a very nervous Italian tailor, forty-two years of age, was first seen in May, 1932, complaining of abdominal fulness and distention and diarrhea. The past medical history was not relevant. He was the father of 11 children. This may have accounted for his consumption of 40 cigarettes daily.

Stomach symptoms began in 1914, with generalized abdominal pains, worse in upper abdomen and referred to lower

He was the father of 11 children. This may have accounted for his consumption of 40 cigarettes daily.

Stomach symptoms began in 1914, with generalized abdominal pains, worse in upper abdomen and referred to lower

dorsal spine on the left side. The pain was accompanied by distention and relieved by defecation. He likewise complained of late postprandial gnawing epigastric pain, relieved by eating or the taking of soda. These two syndromes had recurred at intervals every three or four months. The duration of attacks was from three to six weeks. A bout of diarrhea of five weeks' duration occurred in 1929 and a second attack lasting seven months occurred in 1930. Since then there have been

Fig. 62.—Case III. Extreme irritability of the left colon of the "prediverticulosis" variety.

frequent recurrences of several days' duration, usually after nervous upsets. The patient had never noted mucus, blood or pus in the stools. A diagnosis of duodenal ulcer, probably inactive, was based upon the roentgen demonstration of a markedly deformed duodenal cap and a moderate hyperacidity. Organic colonic disease was ruled out by fecal analysis, sigmoidoscopy and x-ray studies. The passage of the sigmoidoscope into the lower sigmoid was difficult because of spastic

contraction of the bowel. Inflation with air caused epigastric crampy pain quite similar to the upper abdominal pain of which the patient previously complained. This impression of bowel irritability was confirmed by barium enema. The capacity of the colon was one half that of normal. The lumen was narrowed and lacked normal haustral contractions. The whole left colon showed the fine saw-tooth markings which have been described by Spriggs and Marxer as prediverticu-

FIG 63.—Illustrating prediverticulosis in a female patient with long-standing irritable colon symptoms.

losis (Figs. 62, 63). Examination of the gallbladder, blood and urine revealed nothing noteworthy.

**Discussion.**—About 30 per cent of patients with irritable colon symptoms give a history of a duodenal ulcer syndrome (Bockus and Willard). These two symptom groups may occur simultaneously as they did in this patient or they may develop entirely independently of each other. The frequent concomitance of these two conditions may be advanced as an argument favoring an underlying neurogenic or vegetative ab-

normality common to both. In many patients with a colonic neurosis having in addition duodenal ulcer symptoms, the roentgenologic study of the upper tract will show only irritability of the duodenal cap but no ulcer niche. Quite a number of patients of this type subsequently develop a characteristic ulcer defect. This observation likewise lends support to the importance of the neurogenic factor in ulcer pathogenesis.

Further evidence supporting the neurogenic background in our patient was the history of the development of rapid blanching and coldness of the skin of both hands when the arms were elevated. No detailed studies of the peripheral vessels were carried out but there was nothing to suggest organic peripheral vascular disease.

This case illustrates the diagnostic importance of the sigmoidoscopic examination. Spasm and abdominal pain simulating the chief complaint were induced by the introduction of the instrument and inflation with air. Symptoms of great severity have been noted in many patients showing the roentgen signs of so-called "prediverticulosis." This type of bowel silhouette is almost always associated with irritable colon symptoms in my experience.

## CLINIC OF DR. LOUIS TUFT

### TEMPLE UNIVERSITY HOSPITAL

---

#### ASTHMA AND HAY FEVER: THEIR ETIOLOGIC RELATIONSHIP AND CLINICAL IMPORTANCE

THE association of bronchial or allergic asthma with seasonal hay fever is a fairly frequent and generally recognized occurrence. The exact etiologic relationship existing between these two conditions as well as its clinical importance has not always seemed as clear nor has it been sufficiently emphasized. A critical analysis of this aspect of the subject seems worthy of presentation.

Asthma and hay fever may be present in the same patient and bear one of several different relationships. Thus, asthma of an allergic and perennial type may occur in a patient with seasonal hay fever and yet be independent of the latter. The asthma in such instances may be provoked by sensitivity to a food or to an inhalant allergen like dust, feathers, etc., whereas the hay fever symptoms are brought on by contact with plant pollen. The association here is one of coincidence and not one of cause and effect. Such a type is illustrated in the following case report:

**Case I.**—Male, age forty-six, first seen in outpatient allergy clinic in November, 1935, because of asthma, hay fever and eczema. The latter condition (eczema) first began on the face in early childhood and gradually spread to the other parts of the body involving particularly the flexures. It has persisted to present time. Condition is worse in the winter time. In 1930, began having recurring bronchial "colds" consisting mostly of coughing attacks. Since 1932 has had recurrent attacks of asthma worse in the early morning hours. Both the skin condition and the asthma are aggravated by dog contact. In 1932 also developed seasonal attacks of late spring and fall

hay fever of a mild type. These have recurred each year and are not accompanied by asthma or exacerbation of the eczema.

Skin tests revealed definite positive reactions to ragweed, timothy and plantain pollens, important in the etiology of the hay fever and to dust, feathers, dog epithelium, and a number of foods, important in the asthmatic and cutaneous conditions. Patient is at present under allergic treatment and has shown considerable improvement. This is particularly evident in the hay fever symptoms, which have almost completely disappeared. The asthma and eczema still show a tendency to recurrence or aggravation especially after dietary indiscretion and dust or dog contact.

This case report illustrates an instance of perennial asthma and seasonal hay fever occurring in a highly allergic individual and yet bearing no etiologic relationship to one another. As a matter of fact, the connection between the asthma and eczema is much closer since both these conditions are made worse by the same allergens. The hay fever symptoms are really so mild as to be almost completely overshadowed by the other allergic conditions and are responding better to treatment.

The type of asthma present in the latter patient occurs throughout the year and has no seasonal incidence. It is known, therefore, as *perennial asthma* in contrast to those types which are either limited to a certain season of the year or at least begin during the same season of the year, and are therefore referred to as *seasonal asthmas*. Since sensitivity to pollens usually is responsible for the latter type, it is often known as *pollen asthma*.

Seasonal asthma may appear in one of three different forms: (1) it may be the only manifestation which the patient presents or at least the major symptom; (2) it may occur as a complication of a seasonal hay fever, the asthma appearing some time after the onset of the hay fever symptoms and disappearing at the conclusion of the pollinating season; or (3) it may begin as a complication of hay fever but become prolonged for weeks or months after the completion of the pollination period and after the nasal and ocular symptoms of hay fever have disappeared. This type may eventually become perennial.

The occurrence of seasonal asthma without any nasal or ocular manifestations of hay fever is extremely uncommon. Its characteristics, as well as the diagnosis and treatment are similar in every respect to the ordinary uncomplicated seasonal hay fever. The only manner in which these conditions differ is that in the hay fever patient the shock tissue containing the sensitive cells is located in the nasal and ocular mucous membranes, whereas in the individual with pure seasonal asthma, it is located in the lining mucosa of the bronchial tubes. This is exemplified in the following case report:

**Case II.**—Male, age fifty-eight, first seen in September, 1931, with a history of seasonal asthma of twenty-seven years' duration. Attacks begin with dyspnea and wheezing followed later by cough and expectoration. They are particularly bad in the early morning hours between 1 and 7 A. M. and are relieved only by a hypodermic of adrenalin. Attacks come on daily from June 15th until the early part of September when they disappear suddenly and completely. Patient is free of symptoms throughout the rest of the year. *Sneezing, rhinorrhea, or itching of the eyes have never occurred* during these attacks.

Skin tests revealed sensitivity to timothy, plantain and corn pollens. Treatment with a mixture of the extracts of these pollens was advised in consequence.

The important feature in the latter patient is the occurrence of a strictly seasonal asthma in the complete absence of any of the usual symptoms of hay fever. As mentioned previously, this type is very unusual. As a rule when the asthma is seasonal and begins with the onset of the hay fever season, the ordinary nasal and ocular symptoms of hay fever occur at the same time but the asthmatic symptoms are much more prominent than those involving the nose or eyes. This is explained immunologically upon the basis that the shock organ in these patients is located not only in the nasal and ocular mucosae but in the bronchial mucous membrane as well and the cells of both areas are highly enough sensitized to react to contact with the pollen antigen in the form of symptoms of both asthma and hay fever. Consequently, therefore, the

asthmatic symptoms begin at the onset of the hay fever season and at the same time as the nasal and ocular manifestations.

Although the coincident equivalent sensitization of both shock tissues (*i. e.*, upper and lower respiratory) giving rise to asthma and hay fever symptoms at the very onset of the season is possible, it is not the common type by any means. Detailed inquiry into the histories of many of these patients reveals the fact that when the condition first begins, the upper respiratory manifestations exist either alone or are predominant and that the asthmatic symptoms begin some time after the onset of the hay fever. In other words, since the pollen allergen comes in contact with the nasal tissues first, these are the first to react and hay fever symptoms are produced. When the concentration of pollen becomes very marked, the bronchial shock organ of certain patients may then react and asthma results.

The presence or absence of asthmatic symptoms in hay fever patients is dependent, therefore, upon the reactivity of the bronchial shock organ and the concentration of pollen in the atmosphere. If the bronchial tissues are highly reactive, asthma may come on early in the season from ordinary pollen concentrations. If it is not as reactive, asthmatic symptoms may not become evident until the height of the season when pollen concentration reaches its maximum. As a matter of fact, clinical experience has indicated that the onset of asthma at some time during the pollinating season and after the onset of the ordinary hay fever symptoms is the most common manner in which these two conditions are associated. Most of these patients give a history of having had hay fever for some period of time, possibly for years prior to the onset of the asthmatic condition. The symptoms are those of sneezing, watery rhinorrhea, nasal obstruction, itching of the eyes and lacrimation. There is no cough, dyspnea or wheezing. This recurs season after season without any change, the symptoms disappearing completely and often suddenly at the end of the pollinating season. After several seasons and especially at the time at which the pollen concentration of the atmosphere is highest (about ten days to two weeks after the onset), the patient begins to show signs of tracheal or bronchial involvement in the form of an irritating unproductive cough.

This responds fairly well to the ordinary remedies and even if untreated, it diminishes or disappears when the pollen concentration lessens so that it is gone completely along with the other symptoms by the end of the season. This may continue for one, two or more seasons and then the patient will notice that in addition to the cough there is present a constriction or heaviness in the chest, possibly some dyspnea or even a slight wheeze, present especially or only at night. These symptoms likewise disappear at the end of the pollinating season and are neither constant nor pronounced. This syndrome of hay fever symptoms only, followed by the appearance of the irritating cough and in subsequent seasons by definite dyspnea and wheezing, is one which can be obtained by detailed inquiry into the histories of patients with seasonal hay fever and asthma, as for example in the following case report:

**Case III.**—Male, age twenty-nine, first seen May, 1934, because of seasonal hay fever and asthma. The hay fever at first was of the late or autumnal type, coming on about the middle of August and persisting until the first frost. It first began in 1929 and for the first two seasons was accompanied only by the usual nasal and ocular manifestations. In 1931 and again in 1932 patient noticed that two weeks after the onset of the hay fever symptoms, an irritating unproductive type of cough appeared. This lasted until the end of the season and disappeared along with the other manifestations. In 1933 the hay fever symptoms were quite severe and were followed in the early part of September by severe cough, pain in the chest, and dyspnea of a definite asthmatic type. These symptoms were so marked that the patient had to remain in bed for nearly four weeks because of the danger of bronchopneumonia. All symptoms disappeared at the end of the pollinating season. In 1932 patient developed the usual symptoms of early hay fever lasting from the first week in May to the middle or end of June and recurring in 1933. Cough was present in the middle of the season but there was no wheezing associated with it. Except for an occasional winter cold, patient is quite well during the free interval. Hay fever symptoms are markedly aggravated by dust contact during the season, although patient has no symptoms from this contact

at other times of the year. He also notices that the ingestion of such citrous fruits as orange, grapefruit, or lemon during the hay fever season causes itching of the palate or sneezing but not at other times of the year. Except for a history of late hay fever in two maternal uncles, the balance of the history is unimportant.

Skin tests by the intracutaneous method to the important allergens revealed the following:

Marked reactions to: ragweed, birch and walnut tree pollens, and wheat.

Moderate reaction to: house dust and silk.

Slight reaction to: timothy and plantain pollens, orange, cheese and garlic.

Doubtful reaction to: potato, spinach, and crab.

Pollen desensitization with timothy, birch tree and ragweed extracts was begun immediately and continued throughout 1935 and 1936. Marked improvement of early hay fever occurred throughout each year. In 1934, patient obtained more than 75 per cent relief of the late hay fever symptoms and although asthma was absent, slight cough was present for several days at the height of the season. Almost complete relief occurred in 1935 and 1936 and neither cough nor wheezing was present.

This case demonstrates very nicely the commonest type of association between asthma and hay fever. It is important to note that the irritating cough in this patient was present for two seasons prior to the onset of the dyspnea and wheezing. *The appearance of an irritating cough at the height of the season in a patient with the usual symptoms of hay fever should be considered a danger signal warning of a possible asthmatic complication.* Since it has been estimated by various authors that more than 50 per cent of all hay fever patients who do not take treatment eventually develop asthma either of a seasonal or perennial character the importance of the above statement from a prophylactic standpoint becomes obvious. In most of these patients, the hay fever and the associated or complicating asthma are due to sensitivity to the same pollen. The asthma comes on only when the pollen concentration reaches its height or when it is greater than the

nasal shock organ can withstand. The nasal tissues in the hay fever patient as in the normal act as a defender against pollen invasion and it is only when the latter is overpowering in amount that the defense is broken down and the bronchi are involved. This is just as true in this type of case as in a constitutional reaction from a pollen injection, in which asthma may occur as part of the general reaction in a patient with ordinary hay fever who never previously had any asthmatic symptoms. That the pollen sensitivity is likewise responsible for the asthmatic complication is indicated by the fact that as the pollen concentration in the atmosphere lessens, the asthma diminishes and when the pollinating season is terminated, all evidence of bronchial irritation disappears in most patients. It is obvious that the milder the symptoms are in these patients the less tendency there will be for the occurrence of bronchial symptoms. It is for this reason that symptoms of bronchial irritation are the first to disappear in patients receiving pollen therapy. Treatment may not always render the patient completely free of his hay fever symptoms but it will rid him at once of the asthma produced by pollen sensitivity. This was illustrated in Case III as well as in the following patient:

**Case IV.**—Male, age twenty-five, first seen in May, 1934, with a history of late hay fever present since 1922. Symptoms were of the usual nasal and ocular type at first, but for the past few years has had coughing and wheezing spells at the height and toward the end of the season. Treated previously by pollen desensitization with little or no relief. Except for occasional attack of rhinitis in winter, general health is good. Family history reveals migraine in mother, late hay fever in brother and asthma in paternal grandfather.

Skin tests to pollens showed marked sensitivity to ragweed pollen. Pollen desensitization with ragweed extract was begun in May, 1934, and continued throughout the hay fever season and upon an annual basis since. In 1934, patient obtained from 50 to 75 per cent relief of symptoms and though he had no asthma, the cough was present for several days during the height of the season. However, in 1935 and 1936 when

the amount of relief was even greater, neither the cough nor the asthma was present.

*The ability of pollen desensitization to prevent the onset of the asthmatic complication is probably its most outstanding virtue.* Practitioners would do well to emphasize the necessity for pollen therapy for this reason alone rather than for the relief of the hay fever symptoms per se.

For the successful eradication of the asthma in these patients, proper and adequate treatment is essential. Improper treatment obviously will fail in its accomplishment and serve to prolong rather than relieve the condition. By the same token, anything which serves to interfere with the proper treatment, as for example the existence of complicating infections or the presence of additional sensitivities will tend to prevent a successful response to pollen therapy. These extra-pollen factors are more likely to occur in those patients with seasonal hay fever and asthma of long standing who have not had any treatment, or in whom treatment has not been adequate—thus patients may develop symptoms from exposure to dust or feathers or foods or other allergens during the pollinating season and not be affected by them at other times of the year. It is essential, therefore, that patients with seasonal asthma and hay fever who are insufficiently relieved by pollen therapy should be thoroughly investigated to determine the possible presence of factors other than the pollen. This is exemplified in the following case:

**Case V.**—Male, age twenty-one, first seen in March, 1934, because of seasonal hay fever complicated by asthma. Hay fever symptoms first began in August, 1925, and have recurred every year since, lasting until the end of September or the first week in October. Mild nocturnal asthma usually accompanies nasal and ocular symptoms of hay fever toward the end of the season. In June, 1932, developed mild hay fever symptoms of the early summer type, lasting only a short time. Subject to attacks of urticaria attributed to ingestion of tomato.

Skin tests showed definite sensitivity to many allergens—the most important, however, were ragweed, timothy and plantain pollens.

Pollen desensitization with timothy and ragweed extracts was begun in the spring of 1934 and continued throughout the fall. Although the dosage, particularly of the ragweed pollen extract, was increased to a very high point, the patient had no relief of his hay fever symptoms at all and very little relief of the asthma. The injections were continued upon a perennial basis throughout 1935 with little additional relief. Upon closer inquiry it was found that the patient had failed to eliminate those allergens from his diet or environment to which he was sensitive. This was carried out during the 1936 season and in addition injections of dust extract were given. The pollen extract, however, had been maintained at the same level throughout. Under this régime there was marked improvement in 1936 over any previous season, the patient experiencing more than 75 per cent relief and having no asthma.

The latter patient illustrates exceedingly well the manner in which extra-pollen sensitivities may prevent a successful outcome since the pollen dosage during the two years in which no benefit occurred was exactly the same as that during the year when the extra-pollen factors were being taken care of. It also emphasizes the importance of a complete allergic study in those patients who fail to respond to pollen therapy.

These extra-pollen factors seldom aggravate the pure or uncomplicated type of seasonal asthma. They are more likely to influence that type which is associated with hay fever symptoms. Their most common effect in these patients is to produce a prolongation of the asthma beyond the pollinating season. In such instances, the patient usually gives a history of hay fever symptoms only for several seasons, then the hay fever is complicated by asthma which comes on at the middle of the season and terminates at the end. This continues for several seasons when it is noticed that the asthma instead of disappearing at the end of the season is prolonged for variable periods of time beyond the usual limit. These prolongations become greater and greater as the years go by. Since pollen is absent from the atmosphere after the season is over, it is evident that the asthma could not be due to pollen contact, although the latter was responsible for initiating it. Factors other than the pollen obviously must be at fault. These fac-

tors may exist in the form of sensitivity to inhalant, food or bacterial allergens or to infection of the paranasal sinuses or even to such physical factors as heat or cold sensitiveness as suggested by Duke. The following case report is an example of this type:

**Case VI.**—Female, age thirty-one, first seen in December, 1932, because of recurrent attacks of asthma complicating a fall type of hay fever. The latter first began in 1917 following a visit to the country and was accompanied at first by the usual nasal and ocular manifestations beginning about the middle of August and lasting until the end of September. In the last few years, patient has developed asthma which comes on at the height of the season. This disappears usually at the end of the season, but in 1930 and 1931 it has shown a tendency for prolongation into October and during 1932 the asthma persisted in nocturnal form until December. Attacks are aggravated at the seashore or after exertion and are lessened at higher altitudes. For the past three years, patient has had symptoms of early hay fever coming on in May, complicated in June by mild asthma but disappearing usually in July. During the rest of the year, patient is subject to attacks of rhinitis of a bacterial type. Frequent colds as a child. Because of this, patient had two tonsil operations in 1911 and 1916; also, a submucous resection in 1923 and an operation on the ethmoids in 1928. History of asthma in a paternal cousin.

Nose and throat examination, including x-ray of the sinuses, showed the presence of bilateral ethmoidal infection with beginning atrophic changes and also hyperplastic changes of the *left maxillary and frontal sinuses*.

Skin tests by the intracutaneous method showed the following:

Marked reactions to: house dust and ragweed pollen.

Moderate reactions to: timothy and plantain pollens.

Slight reactions to: feathers, goat epithelium, spinach and celery.

Doubtful reactions to: wheat, chicken and flounder.

Allergic studies were carried out in December, 1932, and treatment instituted in January, 1933. By this time, asthmatic attacks had disappeared and patient remained free until May,

1933, when symptoms of hay fever and asthma recurred in spite of dust and pollen desensitization and local nose and throat treatment. Patient was symptom-free in July but symptoms recurred in August and continued in spite of treatment until January 1, 1934, when they disappeared. The same program was repeated in 1934 with the addition of autogenous vaccine administration. Symptoms recurred in May and June and again early in August. On August 15, patient went to the mountains near Kane, Pa., and later to Toronto, Canada. Although symptoms were rather marked in both these places, they were not so severe as at home. The asthmatic attacks continued until October 15 when they disappeared suddenly and completely and did not return again even upon the patient's return to her own residence several weeks later.

In the latter patient, the presence of the sinus infection as well as the sensitivity to other allergens and the effect of climatic changes served to prolong the asthmatic symptoms beyond the hay fever season until late in December. That these factors were of importance is evident from the fact that change of residence was followed by some relief of symptoms and disappearance of the asthma on October 15th.

It is important to recognize this type of patient and to institute treatment early because it is in such a patient as this one that perennial asthma, severe enough to overshadow completely the seasonal manifestations, is likely to develop. Sometimes the transition to perennial asthma is gradual—the patient has the ordinary hay fever symptoms at first; this is complicated after several seasons by asthma which is at first of the strictly seasonal type but later tends to become prolonged beyond the season as the result of extra-pollen factors. If this continues, the asthmatic attacks are not only prolonged beyond the hay fever season but begin to occur throughout the year, so that the patient not only has seasonal asthma but one which is perennial as well. Either of these types may then predominate, although aggravation of the asthma during the hay fever season as well as nasal manifestations usually are evident in most patients. In a few, however, the transition to the perennial type of asthma occurs rather quickly and after only a short period of seasonal symptoms. This type is rather

dangerous because the asthma is likely to terminate as a severe chronic intractable type, as for example in the following case report:

**Case VII.**—Female, age sixty-four, first seen in clinic in December, 1932, with a history of asthma since 1907. At first the asthmatic attacks accompanied the ordinary symptoms of seasonal hay fever of the fall type, beginning in August and lasting six weeks. In 1910, the seasonal incidence extended from June to September and the asthmatic attacks began to assume a perennial character. They became increasingly severe in character so that the patient had to discontinue her occupation as a weaver and have been almost continuous since. Condition is aggravated by exertion and exposure to dust and not improved by change of climate. Patient had migraine at the age of twenty, which lasted several years and subsided spontaneously.

Except for a history of asthma in a maternal aunt, the history is unimportant.

Examination shows marked emphysema with asthmatic râles throughout the chest. Blood pressure 150/90. Heart on x-ray examination showed definite enlargement; the lungs showed changes at the bases attributable either to passive congestion or old inflammatory disease with scarring and pleural thickening and the possibility of bronchiectasis to be considered.

Skin tests by the intracutaneous method showed:

Marked reactions to: house dust, feathers, chocolate.

Moderate reactions to: black pepper.

Slight reactions to: barley, tea, beech tree and timothy pollen.

Doubtful reactions to: wheat, cornmeal, orange, rice, green pea, spinach, peanut, oats, coffee and ragweed pollen.

Patient was placed on appropriate therapy including dust and pollen desensitization for a period of a year but without any change in her asthmatic conditions, the attacks being almost continuous. Patient, therefore, discontinued her visits to the clinic.

A significant feature of the latter case report is the fact that the asthma at first was of the seasonal type and accom-

panied the ordinary symptoms of hay fever. It then became perennial and overshadowed completely the seasonal symptoms. When seen at the clinic the patient was a chronic intractable asthmatic with definite and marked tissue changes and a hopeless prognosis. If treatment could have been instituted when the symptoms were limited to the hay fever season, it is very likely, in view of the favorable response of pollen asthmatics to therapy (as illustrated by Cases III, IV and V), that she would have been spared the untold misery and suffering which ensued in subsequent years. This case emphasizes, more than any of the preceding ones, the necessity for instituting pollen therapy early in hay fever patients as a prophylactic measure against a complicating asthma which may be of a severe or intractable type.

#### SUMMARY

Asthma appearing in patients who have seasonal hay fever may occur either independently of the latter and have no etiologic connection, when it is known as *perennial asthma*, or, as is more common, it may occur as a seasonal manifestation and have a definite etiologic relationship. The latter form is referred to often as *seasonal* or *pollen asthma*, since it occurs in pollen-sensitive individuals. Seasonal asthma may appear in one of three ways: (1) it may appear as the only manifestation of pollen allergy, (2) as an accompanying manifestation of seasonal hay fever, or (3) as a complication of hay fever.

The first type, constituting a true pollen asthma, is one in which the patient has asthmatic attacks recurring regularly each season in the same way as in hay fever and subject to the same variations but not accompanied by nasal or ocular symptoms. In other words, the site of the affection or shock tissue involves only the bronchial mucous membrane.

In the other two types, the patient has the ordinary symptoms of hay fever but in the middle or toward the end of the season develops asthma of a mild or severe character. The onset of these symptoms may be indicated frequently by the presence of cough or constriction in the chest without definite asthma. These symptoms recur each year with increasing intensity until definite asthmatic attacks begin.

In patients belonging to the second group, the asthma is due entirely to the effect of the large amount of pollen acting not only on the nasal shock tissue but upon the bronchial mucosa as well. The asthma in these patients usually disappears rather suddenly with the cessation of the hay fever symptoms at the end of the season.

In patients comprising the third group, the asthma is the result of either specific or nonspecific factors other than the pollen itself; thus, such physical agents as a cold wind or the inhalation of such allergens as dust, feathers, orris root, etc., or the ingestion of certain allergenic foods, or the presence of infection of the sinuses may serve to provoke asthma in these individuals. Such extra-pollen factors may cause asthma during the hay fever season or prevent a satisfactory response to treatment, even though they have little or no effect upon the patient at other times of the year. They most frequently act to prolong the asthmatic symptoms beyond the hay fever season and for variable lengths of time after the nasal symptoms have disappeared.

These patients are especially prone to develop a perennial type of asthma which may completely overshadow the seasonal manifestations or may in some patients develop into the severe chronic intractable type of asthma so resistant to treatment. Since asthma is the first symptom to disappear in properly treated cases, the importance of early diagnosis and of the institution of proper and adequate treatment in patients with hay fever, either alone or accompanied by asthma, becomes obvious from a prophylactic standpoint.

## CLINIC OF DR. DAVID L. FARLEY

### PENNSYLVANIA HOSPITAL

---

#### ACUTE INFECTIOUS MONONUCLEOSIS

THE name "Drüsenfieber," glandular fever, was given by Pfeiffer<sup>12</sup> in 1889 in his first description of the disease which we now call "infectious mononucleosis." Pfeiffer no doubt gave the disease this name because, as is well known, the lymph nodes are affected. It seems better, since lymph nodes are not properly referred to as "glands," to use the term "infectious mononucleosis." Even this term is slightly misleading because of its implication that the abnormal cells found in the blood picture of this condition are always "monocytes."

The etiology of infectious mononucleosis is unknown. The pathogenesis is obscure. Opinion varies between two points of view as to the mode of production of the blood picture peculiar to this disease; that it results from the characteristics of the organism specifically producing the disease; or that it is a picture which may result from tissue reaction in response to more than one etiologic agent.

Until recently the histologic features of the involved lymph nodes were not well known because of the paucity of biopsic and necropsic material. An article by Downey and Stasney<sup>7</sup> goes very fully into the pathologic histology. In a series of biopsied lymph nodes of 8 cases of infectious mononucleosis various stages in the lymph node histology were studied. There was a hyperplasia of reticulum involving both the sinus reticulum and the general reticulum. The hyperplasia of small lymphocytes in some of the nodes was suggestive of early lymphatic leukemia with the important exception that the architecture of the nodes never showed complete obliteration as is seen in lymphatic leukemia, and the capsule of the lymph nodes was not invaded. It appeared that the peculiar atypical cells which were seen in smears from the peripheral blood originated in the lymph nodes, since so many of these atypical

and leukocytoid lymphocytes were seen in the lymph node sections.

The point of view that the so-called "abnormal cells" found in the blood smears are lymphocytes rather than monocytes is borne out by the studies of Stuart, Burgess, Lawson and Wellman<sup>13</sup> who concluded from the use of the supravital staining technic of Wilson and Cunningham<sup>17</sup> that the abnormal cells are lymphocytes. They<sup>13</sup> believe that in this disease a strong stimulus to cell division in the germinal centers in the lymph nodes and spleen results in the peculiar appearance of the lymphocytes in the circulating blood.

Infectious mononucleosis becomes of importance to the practicing physician because of the resemblance of the blood picture at times to that of the more serious and uniformly fatal disease, leukemia. This resemblance leads to great alarm over the prognosis in the particular patient until it is found that the condition is really the relatively benign disease, infectious mononucleosis. The brilliant work of Paul and Bunnell<sup>11</sup> who showed that the so-called "heterophile antibodies" are greatly increased in infectious mononucleosis, together with the observations of Downey and Stasney<sup>7</sup> and Stuart, Burgess, Lawson and Wellman,<sup>13</sup> has stimulated the interest of the immunologist in this disease. There seems little doubt that serum from individuals suffering from infectious mononucleosis will agglutinate sheep cells in much higher dilution than serum from patients suffering from other infectious diseases—with the possible exception of serum sickness. The observations of Paul and Bunnell<sup>11</sup> have been verified by Bernstein,<sup>3</sup> Davidsohn,<sup>5</sup> and others. There is, however, some question as to whether the heterophile nature of the antibody in infectious mononucleosis can be unreservedly accepted.<sup>13</sup>

The details of 12 cases of infectious mononucleosis follow:

**Case I.**—C. R. T., age twenty-eight, admitted August 8, 1933, discharged August 29, 1933.

The patient was a young physician, a hospital resident. The onset of his illness was after a strenuous tennis game. He was affected with a sore throat, fever, and malaise. He had a constant fever for six days and for several days thereafter his fever continued with a slight rise to 99° F. in the afternoon. His pulse was never higher than 110 per minute. The

physical examination of the patient showed the throat to be diffusely reddened and edematous with much lymphoid hyperplasia of the pharynx. A definite gingivitis was present. The gums bled easily. Small ulcers developed in the mouth on each side of the posterior part of the hard palate. Smears from the lesions of the mouth, throat, and gums showed Vincent's bacilli and chains of streptococci, green streptococci predominating. Sodium perborate and gentian violet were used for the mouth lesions. Ulcers also developed on the tip of the tongue and several petechiae developed on the mucosa covering the hard palate. All the mouth lesions were very painful. In the neck the anterior lymph nodes were enlarged and tender. There was no enlargement of the postcervical nodes but a slight enlargement of the nodes in axillae and groins was evident. The enlarged lymph nodes persisted during the fever period. The spleen was enlarged and easily palpable. This enlargement persisted throughout the period of fever. The urine analyses showed nothing abnormal. The blood sugar, August 16, 1933, taken in the morning after fasting, showed 84 mg. per cent.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Eo.	Bas.	Lymph.
8/8/33	92	4700	7,150	28	2	..	70
8/8/33			10,400	35	..	..	65
8/8/33			9,900	37	..	..	63
8/10/33			14,000	34	..	..	small 26 66 large 40
8/11/33			8,500	30	..	..	small 19 70 large 51
8/12/33			9,900	48	..	..	small 28 52 path. 24
8/13/33			9,500	39	..	..	small 30 61 large 31
8/14/33			9,300	38	..	..	small 28 62 path. 34
8/15/33			8,000	56	..	..	small 32 44 path. 12

The following notation was made on the second count dated 8/8/33. Smears showed normal R. B. C. The 65 per cent lymphocyte count included all the monocytes. At least half of these cells were large cells with irregular nuclei and deep-staining chromatin. Many were vacuolated. They appeared to be of lymphocytic origin and typical of the cells seen in infectious mononucleosis.

**Case II.**—C. E. S., age twenty-six, admitted April 4, 1929, discharged April 13, 1929.

The patient was a young physician, at the time a hospital resident. For six days the patient had a prodromal period of chilliness and malaise, then the onset occurred with a shaking chill on April 3, 1929. At this time the temperature was 101° F. The patient's fever varied from 99° to 100.5° F. over a period of six days and then became normal. Physical examination showed the posterior cervical lymph nodes to be slightly enlarged, and an increased area of splenic dulness to percussion was noted. The axillary and epitrochlear nodes were not palpable.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Eo.	Bas.	Lymph.	M n.
4/ 7/29	10.9	4280	....	f. 23 28 nf. 5	..	..	64	8
5/15/29	..	....	8000	f. 63 76 nf. 13	.	1	19	4
8/ 1/29	9.3	4590	7300	72		..	25	3

**Case III.**—P. M. B., age twenty-two, admitted May 14, 1935, discharged May 20, 1935.

The onset occurred four days after a tooth extraction. At this time there was a feeling of a lump in the throat when swallowing. The patient continued his usual activities until he was told that he had a tonsillitis. At this time, May 14, 1929, he had a tender sore throat and "lumps" in his neck. His throat was found to be congested, there was a bilateral moderate cervical lymphadenopathy. His spleen was distinctly palpable. For four days the patient's temperature varied from

99° to 100° F., and then became normal. The urine analyses were negative.

The blood counts were as follows:

Date.	Hb.	W. B. C.	Poly.	Eo.	Bas.	Lymph.	Mon.
5/15/35	..	9,400	f. 10 26 nf. 16	3	..	52	19
5/13/35	..	12,500	f. 26 36 nf. 10	..	..	34 lymph. 40 path.	

**Case IV.**—H. S. F., age 19, admitted January 10, 1930, discharged January 19, 1930.

The patient was a worker in the post office. The onset of his illness occurred after physical exhaustion from prolonged hours of Christmas holiday mail rush. He was affected with chills and malaise; his throat felt irritated and dry but not definitely sore. There was no coryza or nasal discharge. For about two weeks his temperature varied from normal to 104° F. The physical examination of the patient showed a marked bilateral posterior cervical lymphadenopathy. The mucosa of the pharynx and the posterior part of the mouth were injected but showed no other evidence of soreness. The spleen and liver were not palpable. The urine analyses were negative. x-Ray of the sinuses was negative.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Eo.	Bas.	Lymph.	Mon.
1/10/30	90	4700	25,000	16	..	..	26	58
1 14 30	.	....	11,000	40	..	..	32	28

**Case V.**—E. C. A., age twenty-five, admitted January 7, 1924, discharged February 4, 1924.

For a month before the onset the patient felt "run down," tired easily and felt exhausted. At the time of the onset there was tenderness in the back of the neck. At this time he had a fever and headache and slight epistaxis on blowing his nose. His temperature was rather prolonged, recorded from January 7 to January 22 (three weeks), and varied from 99.2° to

102.3° F. Physical examination showed a slightly congested pharynx. The lateral and posterior cervical lymph nodes were distinctly enlarged, discrete, hard and tender. The lymph nodes in the axillae and inguinal regions were greatly enlarged, discrete and tender. The epitrochlear nodes were readily palpable. The nodes varied in size from 0.5 to 1.5 cm. in diameter. There was expectoration of small amounts of blood, probably from the nasopharynx. The liver was enlarged, being 7 cm. below the costal margin in the right midsternal line. Jaundice was marked. The spleen was enlarged. There were no skin eruptions. The patient was irrational at times. Ten days after the onset the lymph nodes became smaller. An oxydase stain of the predominating large cells in the blood smears showed an absence of granules, in the cell cytoplasm of the abnormal cells. The spleen remained palpable for at least three weeks after the onset. The urine showed at various times bile and a heavy cloud of albumin.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Lymph.	Mon.	Eo.	Bas.	Path.
1/19/24	85	5540	11,000						
1/11/24	..	.	.	23	7	2		2	70
1/13/24	.		16,400	13	12		2	3	60
1/15/24	90	5470	10,500	coagulation time 5 minutes.					
1/17/24	.	.	18,800	31	6	1			62
1/23/24	85	4340	9,400	12			2		85
1/28/24	85	4920	6,700						
2/ 3/24	80	4600	5,600	22					78
12/17/29	98	6140	7,800	37 5	52	7 5	2 5		0 5
7/16/34	87	4740	5,600	54	13 5	2	0 5		

This patient was followed through the courtesy of Dr. John B. Barnwell. The blood counts of 12/17/29 and 7/16/34 were made by Dr. Raphael Isaacs who noted that "immature lymphoid cells were present. On both occasions, but more marked on the examination of 12/17/29, cells of the infectious mononucleosis type were present."

**Case VI.**—W. H. L., age twenty-five, admitted June 28, 1925, discharged July 27, 1925.

At the onset of his illness the patient had chills, headache and malaise with enlarged inguinal nodes on the right side. He was found later to have a chancre which produced a positive Wassermann reaction of the blood. He began to run a slight fever and developed a sore throat. The temperature varied from 99° to 104.4° F. for seventeen days. Physical examination showed a congested sore throat, with no definite lesions. The lymph nodes in the postcervical and anterior cervical chains were slightly enlarged. There was a slight generalized enlargement of the lymph nodes. The spleen was questionably palpable. The liver was not enlarged and there was no jaundice. Urine analyses showed a cloud of albumin on two occasions, but no casts.

The blood counts were as follows:

Date.	Hb.	W. B. C.	R. B. C.	Poly.	Lymph.	Eo.	Ab. Mon.	My.	Bas.
6/29/25	100	14,400	5200						
7/ 5/25	.	13,250							
7/ 8/25	.	14,050	....	8	35	..	57		
7/ 9/25		.. ..	....	14	48	..	33		
7/15/25	..	9,000	....	11	48	..	27	5	1
7/25/25	.	.....	....	31	59	..	..	9	1

**Case VII.**—M. S., age twelve. The patient was a school-boy. On admission he was suspected of having typhoid fever. The onset of his illness was with malaise and fever and indefinite localizing symptoms. Physical examination showed generalized lymph node enlargement. The spleen and liver were enlarged and palpable. There were no spots on the skin. His temperature was constantly elevated for five days. At times it was as high as 103.3° F. It gradually receded to normal. x-Ray pictures showed enlargement of the mediastinal lymph nodes. Urine analyses were negative.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Lymph.	Mon.
6/5/00	80	4600	7000	26	70	4

**Case VIII.**—A. W., age twenty-four, admitted April 30, 1929, discharged May 27, 1929.

The onset of her illness was with "hives." There was no history of food indiscretion or eating shellfish and no history of taking drugs of any kind. She had headache, chilly sensations and pain over the small of the back and in the joints. Physical examination showed the cervical and axillary lymph nodes to be enlarged, the largest being about 0.5 cm. in diameter. The liver was enlarged. Her temperature varied from normal to 102° F. for twelve days and then remained normal. Bile was present in the urine on two occasions.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Eo.	Bas.	Lym.	Mon.
5/ 3/29	13.5	4760	19,800	17	..	..	29	52 Platelets abun.
5/ 4/29	....	....	26,700	7	..	..	31	62
5/ 6/29	...	....	28,600	3	..	.	35	62
5/ 7/29	.. .	....	36,100	7	.	..	23	70
5/ 8/29	....	...	34,100	3	.	.	19	78
5/ 9/29	14.9	4200	28,800	7			8	85
5/10/29	....	....	28,200	9	1		11	79

5/20/29			11,500	21	1		56	22
5/22/29		.	9,200	16			76	8
5/24/29	.	.	7,600	11		1	65	24

**Case IX.**—J. B., age twelve, admitted May 22, 1928, discharged June 1, 1928.

The patient was a schoolboy. The onset of his illness occurred on May 20, 1928, with pain and swelling below the angles of the jaw. The physical examination showed an acute adenitis and a nonexudative tonsillitis. The lymph nodes were discrete, fairly-firm and quite tender. The spleen was palpable. The axillary and inguinal lymph nodes also were palpable. His temperature for three days varied from normal to 103° F. Urine analyses were negative.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Eo.	Large lymph.	Lymph.	Mon.
5/22/28	12.5	4480	7,800					
5/23/28	...	...	11,400	15	..	4	40	4
5/24/28	..	....	9,400	21	..	30	49	
5/26/28	..	...	8,800					
6/ 1/28	.		7,300	19	1	7	71	2

**Case X.**—E. B., age thirty-one, admitted July 19, 1928, discharged July 29, 1928.

For a week preceding the onset there were tenderness and slight enlargement of lymph nodes under the angles of the jaws. The onset was with sore throat. The physical examination showed both tonsils red, swollen and covered by follicular white exudate. There was bilateral enlargement of the anterior cervical lymph nodes, varying in size from 0.5 to 0.75 cm. The spleen was enlarged, firm and palpable. The liver was increased in size, it was palpable about 3 inches below the average normal level. The patient had a fever for six days varying from normal to 104° F. Urine analyses were negative.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Eo.	Bas.	Lymph.	Mon.
7 20 28	14	4600	18,000	13	..	1	73	13
7 21 28			19,300	11	1	..	58	30
7 28 28	13	4370	9,900	28	1	1	59	11
8 20 28	13	4300	13,200	62	..	..	19	19

**Case XI.**—J. F. W. developed infectious mononucleosis as a complication of his convalescence from an operation for hemorrhoids. The data are incomplete.

The blood counts were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Lymph.	Mon.	Eo.	Bas.
10/ 3/34	80	4250	6,400	21	73	15	..	1
10/ 5/34	..	....	6,800	26	48	18	6	2

10/ 9/34	80	....	6,300	41	50	8	..	1
10/10/34	80	....	6,500	30	64	15	..	1
10/14/34	..	....	7,600	31	57	9	.	3
11/16/34	..	.. .	8,800	54	42	4		
1/21/37	..	....	11,100	59	38	3		

**Case XII.**—Miss J. B. Patient was a twenty-year-old college girl who became ill on December 27, 1936, with malaise, sore throat, and fever, and generalized aches and pains. Two days later, when seen at her home her temperature was 101.2° F. Her pharynx was very red. The tonsils had been previously removed, and there were small palpable nodes in both posterior cervical chains and in the angle of the jaw on either side. Her chest was entirely clear, her heart was not enlarged. There were no heart murmurs. The abdomen was soft, the liver and spleen were not felt. The extremities showed nothing abnormal. The fever remained in the neighborhood of 101° F. for three days, then gradually subsided by January 7, 1937. During this time the lymph nodes became much more prominent, then gradually subsided. The spleen also became palpable. The blood counts for this period were as follows:

Date.	Hb.	R. B. C.	W. B. C.	Poly.	Lymph.	LL.	Mon.	Eo.	Bas.
12/31/36	..	....	3,500						
1/ 4/37	..	....	4,000	68	24	1	7		
1/ 6/37	80	4690	11,600	38	61	4	7	1	
1/ 9/37	..	....	11,700	16	74	9	2		
1/16/37	85	5450	10,200	16	75	3	3	1	2

She returned to college on January 19, 1937, whereupon her fever recurred and reached 99.3° F. She was seen again on January 25, 1937, when the blood count was:

6400            21            72            2            5            1

The lymph nodes in the neck were very much smaller and the spleen was no longer palpable. After remaining in bed for two days the temperature became normal again and she again returned to college. The temperature remained normal.\*

#### DISCUSSION

Infectious mononucleosis occurs more frequently in young adults. Intrinsically the disease is of importance because of its resemblance to the extremely serious condition, lymphatic leukemia, rather than in itself, since it is very rarely fatal and leaves no residual incapacity.

The spleen and lymph nodes usually are enlarged. In the severe cases the liver is increased in size and there may be jaundice. Aside from the resemblance to an ordinary upper respiratory infection the outstanding findings are in the blood picture. This shows as a rule an increase in the total number of leukocytes with a disproportionate percentage of mononuclear cells. This term, "mononuclear," should be understood as referring to morphology rather than to the existence of an excess of so-called "monocytes." In other words, the excessive percentage of single nucleated cells may resemble more the lymphocyte. In the exceptional case the total leukocyte count may not be above 10,000 per cubic millimeter.

Most patients show no abnormality in smears from the

\* Reported through the courtesy of Dr. Lawrence S. Carey, 1 Cedar Lane, Highland Park, Pa.

blood for any considerable time after recovery. In the severe cases, however, the presence of immature lymphocytes may persist for a long period. Many of the cases reported here have been followed, and in none of them was there any tendency to develop leukemia. In Case V, immature lymphocytes could be recognized ten years after apparent recovery.

Ulcerations in the mouth cavity and throat may occur but, as a rule, the sore throat complained of shows only congestion of the mucous membrane. Vincent's spirillae are seen in the smears from the throat in many cases but probably this organism is a secondary invader and not concerned in the etiology of the disease. Weak gentian violet solution or a solution of sodium perborate is useful for local treatment of the throat and mouth lesions.

Lymphadenopathy may be generalized but most often the cervical nodes are most prominent. The enlargement of the lymph nodes persists during the period of fever and then completely subsides. In none of the cases reported was there any evidence of nephritis.

The fever as a rule is not high but inclines to be more persistent than that observed with an ordinary upper respiratory infection. The tendency to persistence of an evening rise of temperature may be a source of worry to the patient's family and an embarrassment to the physician. In the exceptional case the temperature may rise to 105° F. An average duration of fever is difficult to arrive at. There was a variation from three days to three weeks in the cases I have observed.

The existence of jaundice means, as a rule, that the case is more severe than the average. The mediastinal lymph nodes may be enlarged as shown by fluoroscopic examination of that region.

### SUMMARY

Twelve cases of infectious mononucleosis are reported with some review of recent literature on this subject.

## CLINIC OF DR. RALPH M. TYSON

### TEMPLE UNIVERSITY SCHOOL OF MEDICINE

#### PROBLEMS IN INFANT FEEDING

GREAT progress has been made during the last ten years in the ability of the physician to feed infants satisfactorily. It seems that this improved ability on the part of the physician to feed infants successfully on artificial feeding has caused us to forget the significance of breast feeding in the development and well-being of the infant.

In these times of stress and strain on the part of mothers in a certain economic group, there has been a growing tendency to refuse to nurse their infants on the breast. The excuses offered are many and varied. Undoubtedly the attitude of the obstetrician, and the knowledge or lack of it on the part of special obstetrical nurses, has a great deal to do with the success or failure of breast feeding in this class. A few years ago Dr. Grulee of Chicago, with several of his assistants, presented some very valuable records in reference to the morbidity and mortality in breast-fed and bottle-fed infants.

TABLE 1

MORBIDITY AND MORTALITY; BREAST-FED vs. BOTTLE-FED

	Cases.	Per cent.	Morbidity.
Breast-fed .....	9749	48.5	37.4
Breast and bottle.....	8605	43	58.8
Bottle-fed.....	1707	8.5	63.6
Total cases.....	20,061		
Total deaths.....	218		
Breast-fed .....	15	6.7	
Breast and bottle .....	59	27.2	
Bottle fed .....	144	66.1	

Table 1 summarizes some of these differences in a very clear way. It tells a story that we need to emphasize over and

over again. Those of us who have had experience with newborn babies believe sincerely that most of the mothers can nurse their babies if they only would be willing to make a satisfactory effort. It can be clearly seen how the morbidity increases as the number of breast-fed babies in the group decreases. It can be readily seen that the mortality rate is ten times as high in those that were bottle-fed exclusively as in those who were breast-fed exclusively. Statements have been made from time to time regarding the greater resistance to disease that the breast-fed infant has, but our teachings have not been as effective as they might be for doctors, the nurses and mothers. It should be clearly understood what it means to the child to wean it from the breast.

In these days of simplified infant feeding there is not much question about the success of formula feeding. At the present time the exact needs of the individual child for the several food elements are quite definite. Enough scientific studies have been made to prove these statements and the data which follow:

TABLE 2

## BASIC NEEDS IN INFANT FEEDING (MINIMUM REQUIREMENT)

						Calories.
Fat...	2	Gm. per pound per day	$\times 9.3$	=	18.6	
Protein...	1.5	" " " " "	$\times 4.1$	=	6.1	
Carbohydrates...	5.0	" " " " "	$\times 4.1$	=	20.5	
						45.2

Whole milk  $1\frac{1}{2}$  ounces contains { Fat, 2 Gm.  
Protein, 1.5 Gm.  
Carbohydrates, 2 Gm.

Sugar added, 1/10 ounce per pound per day.

It has been shown that the basic needs of the growing infant are 2 Gm. of fat,  $1\frac{1}{2}$  Gm. of protein and 5 Gm. of carbohydrate per pound per day. This is necessary to meet the minimum requirements of the average infant. In caloric values this amounts to 45 calories per pound. It is doubtful if any infant will grow on less than 45 calories per pound per day, and these calories should be secured by the above arrangement of the necessary food elements, so that fat makes up about 35 per cent, protein 15 per cent, and carbohydrates 50 per cent of the total caloric need.

To put these figures into terms that can be easily understood by the parent, it is known that  $1\frac{1}{2}$  ounces of whole milk contains 2 Gm. of fat,  $1\frac{1}{2}$  Gm. of protein, and 2 Gm. of carbohydrate. The amount of carbohydrate is inadequate to what is believed necessary, so the 3 additional Gm. of carbohydrate must be added to the formula. This amounts to  $\frac{1}{10}$  of an ounce of sugar per pound per day.

TABLE 3

MINIMUM AND MAXIMUM REQUIREMENTS PER POUND OF EXPECTED WEIGHT

Whole milk.....	$1\frac{1}{2}$	up to 2 ounces
Sugar.....	$1/10$	up to $\frac{1}{8}$ ounce
Fluids.....	3	up to 2 ounces
Calories .....	45	up to 60 cal.

Quite a large number of babies will not grow satisfactorily on the minimum requirements as stated, and it is necessary to increase the amount of milk up to 2 ounces and the amount of added sugar up to  $\frac{1}{8}$  of an ounce per pound per day. This increases the caloric values up to 60 calories per pound per day. The average young infant will need about 3 ounces of total fluids per pound per day. This amount of fluids gradually decreases during the first year of life.

TABLE 4

ENERGY REQUIREMENTS (DISTRIBUTION)

Basal metabolism (resting).....	25	calories per pound.
Activity.....	10	" " "
Growth.....	7	" " "
Unutilized food.....	6	" " "
Specific dynamic action.....	4	" " "

#### Variation

Low in first few weeks:

First to fourth months.....	50 to 60	calories per pound
Fourth to eighth months.....	45 to 50	" " "
Eighth to twelfth months.....	40 to 45	" " "

The energy requirements of the average infant are stated in Table 4, and are distributed according to the specific needs of the child and include basal metabolism, activity, growth, unutilized food and specific dynamic action of food substances,

with particular reference to proteins. There is considerable variation in the energy requirements of infants during the first year. It is highest during the first four months, and decreases toward the end of the first year. The needs of the infant during the lying-in period are particularly low. It is this fact that has convinced most of us who deal with the newborn that the full caloric requirements of the newborn baby should not be met. There should be a gradual increase in the amount of food offered to the infant in this period. Shortly after the newborn period, the greatest amount of food is required. This is the period in which we have the most rapid growth.

In Table 5 some approximate measures of five different types of carbohydrates are given. It is to be remembered that

TABLE 5  
APPROXIMATE REQUIREMENTS; SUGARS

Cane sugar . . . . .	1 ounce equals 2 level tablespoonfuls
Karo syrup . . . . .	1 " " 2 " "
Lactose . . . . .	1 " " 3 " "
Dextrimaltose . . . . .	1 " " 4 " "
Mellin's food . . . . .	1 " " 4 " "

The caloric values of sugar are all the same.

#### Caloric Values

	Calories.
1 ounce any sugar yields . . . . .	120
1 ounce whole milk yields . . . . .	20
1 ounce skimmed milk yields . . . . .	10
1 tablespoonful cereal yields . . . . .	25

the caloric values of these sugars are the same. The caloric values of whole milk, skimmed milk and cereals may be found in this table.

To feed young infants according to the method previously described does not always mean that these same infants will do well. It is to be remembered that cow's milk is not so readily digested as is breast milk. This is probably more a mechanical problem than it is a chemical one. It is felt at the present time that the difficulty in digesting cow's milk is due to the large, tough curds that are formed in the stomach and the difficulty that the digestive juices have in penetrating these curds.

Table 6 outlines five ways that aid materially in the ability of the child to digest cow's milk. It is obvious, of course,

TABLE 6

## AIDS TO DIGESTION OF COW'S MILK

1. Diluting with water.
2. Diluting with cereal water.
3. Boiling for three to five minutes.
4. Addition of alkalis.
5. Addition of acids.

All methods concerned with producing softer and smaller curds.

that if too much dilution with water is attempted, the total quantity of the formula used will prohibit the giving of sufficient calories to meet the needs. All of the methods shown in Table 6 are concerned mainly in producing smaller and softer curds. The addition of cereal water has an added advantage in changing the formula to a colloid solution. It seems that the intestinal tract is better able to digest such solutions than it is crystalloid solutions. It is the practice of most pediatricians to boil all milk that is given to young infants, feeling that this is necessary not only to inhibit the large, tough curd formation but also to insure a sterile solution. The use of alkalis has to a large extent gone out of vogue, for it is now known that many young infants do not have sufficient hydrochloric acid for their own digestive needs, hence the use of alkalis should be limited to those cases in which a hyperacidity appears to be present. In such circumstances remarkable success in the feeding of difficult cases can be secured.

The common acids that are used are the U. S. P. lactic acid, about 2 drops per ounce of milk in the formula; citric acid as found in orange and lemon juices, requiring about 1 ounce of orange juice or  $\frac{1}{2}$  ounce of lemon juice for the total formula each day. The addition of these acids has revolutionized infant feeding, particularly in the difficult cases and in the malnourished infant. In the last few years the use of evaporated milk has in many places supplanted fresh certified milk. It is to be remembered that 1 ounce of evaporated milk is equivalent to 2 ounces of fresh milk in caloric values.

TABLE 7

## FEEDING THE NORMAL NEWBORN

1. No cow's milk in the first two or three days.
2. Begin with smaller amounts—weaker dilutions.
3. Wait for favorable signs before increasing.
  - No vomiting.
  - Hunger.
  - Normal stools.
4. Then increase slowly, taking ten to fourteen days to reach normal requirements.

## Example

Whole milk.....	7 ounces—8—9—10—11
Lactose.....	1 level tablespoonful—2—2½—2¾
Boiled water.....	14 ounces—13—12—11—10
7 bottles of 3 ounces—feed every three hours.	

Specific problems in infant feeding will arise from time to time for the general practitioner and the pediatrician. Feeding the normal newborn infant is such an important problem and so frequently misunderstood that it seems wise to emphasize some important points in such procedure. It is the author's opinion that no cow's milk, or very little, should be given in the first two or three days of life. It is always wise to begin with smaller amounts and weaker dilutions during this period, and to wait for favorable signs, such as no vomiting, hunger, and the appearance of normal stools, before increasing the amount of cow's milk. Increases should be made slowly, over a period of possibly from seven to fourteen days, before reaching the full caloric requirements of the infant in question. It seems wise not to provoke indigestion in the newborn infant, and to guard the normal physiologic functions of the gastro-intestinal tract even at the expense of weight loss or slow weight gain. It is much easier to prevent indigestion than it is to overcome it in the very young infant. It does not seem wise to the author to institute cow's milk feeding in the first two or three days before the mother's milk has appeared in the breasts. Complementary feedings should not be given to breast-fed babies until sufficient time has elapsed to see whether the baby can be successfully breast-fed. If the weight loss continues, however, and exceeds 10 per cent of the birth weight, additional food must be given under these

circumstances. It is the author's opinion that adequate amounts of water, with perhaps a weak dilution of carbohydrate, are all that is needed by the average newborn baby in the first two or three days after birth. It is perfectly true that when a young infant is started on a formula such as shown in Table 7, it will not take all of the 3 ounces at every feeding. It is allowed to take as much of the amount specified as it seems to desire. Attempts are not made to force extra feeding on these young infants.

After an experience in dealing with about 20,000 newborn babies that have been under the author's supervision in the past twelve years, I have come to the conclusion that this method of feeding the newborn is a highly satisfactory and safe procedure. Of course, it goes without saying that newborn babies differ decidedly in the amount of food they will take and the amount that they are able to digest. This method will feed fully 90 per cent of all the normal full-sized newborn infants.

In Table 8 the problems in feeding the premature child are expressed. It seems to be the universal opinion that the best

TABLE 8

FEEDING THE PREMATURE CHILD BY BOTTLE—BRECK FEEDER—DROPPER OR TUBE

1. Water 1 to 4 ounces every three hours—first day
  2. Breast milk best of all foods.  $\frac{1}{2}$  to 1 ounce every three hours.
  3. Skimmed milk..... 8 ounces  
     Lactose..... 1 tablespoonful  
     Lactic acid..... 16 drops.  
         Offer up to 1 ounce every three hours.
  4. Similac . . . . . 3 tablespoonfuls  
     Boiled water..... 8 ounces.  
         Offer 1 ounce every three hours.
- Favorable signs:* No vomiting, no distention.  
                     Normal stools—hunger.  
                     Increase quantity—quality.  
                     Add cream slowly.

food for the premature child is breast milk, which should be given either by bottle, Breck feeder, medicine dropper, or by gavage. Very few premature children are ever put to the breast during the first week of life. In the first twenty-four hours,

water or a weak carbohydrate solution is all that is necessary. If breast milk can be secured, 1 to 4 drachms may be given every three hours. In the absence of breast milk the use of skimmed lactic acid milk, with added sugar, has proved very successful. Some of the powdered milks, such as Similac, have proved very useful in such cases. It is more important in premature infants to wait for favorable signs, such as no vomiting, no distention, the appearance of hunger, and normal stools, before increasing the quantity and quality of the formula.

In Table 9 there is a satisfactory formula for feeding a normal three-month-old child that weighs 12 pounds. It is

TABLE 9

## FEEDING NORMAL THREE-MONTH-OLD CHILD WEIGHING 12 POUNDS

		Calories.
Whole milk.....	21 ounces	= 420
Lactose.....	4½ tablespoonfuls	= 180
Barley water..	9 ounces	—
		12)600
		50

6 bottles of 5 ounces—Feed every three hours. 6—9—12—3—6—10

Another way of expressing it:

	Calories.
50 calories per pound . . . . .	12 × 50 = 600
Sugar ½ ounce per pound . . . . .	1½ × 120 = 180
Difference.....	420
420 calories divided by 20 = 21 ounces milk.	

noted that 1¾ ounces of whole milk per pound body weight, and ⅓ ounce of lactose are given, using barley water as a diluent in this case to secure a colloid solution. The amount of barley water used is small and scarcely enters into the caloric values. It is estimated that this child should receive about 50 calories per pound. The amount of food at a feeding that a child can take without disturbance is about 2 ounces more than it is months old, up until the child is six months of age. Using this same principle, a formula can be easily calculated for any normal infant regardless of its age and weight.

In Table 10 a formula for a vomiting baby weighing 7 pounds is suggested. Of course, under such circumstances a diagnosis of pyloric obstruction should be anticipated, but until a proper diagnosis can be made this formula of skimmed

TABLE 10

FORMULA FOR VOMITING BABY WEIGHING 7 POUNDS

		Calories.
Skimmed milk.. . . . .	16 ounces	$\times 10 = 160$
Lactose.. . . . .	3 level tablespoonfuls	$\times 40 = 120$
Farina. . . . .	2 level tablespoonfuls	$\times 25 = 50$
		<u>7)330</u>
		47

Cook farina in milk two hours.  
 Evaporate to 12 ounces.  
 Add sugar.  
 Divide into 6 bottles of 2 ounces each.  
 Feed every four hours.

milk, lactose, and farina can be used to advantage. It is important to cook the farina for a two-hour period and evaporate the skimmed milk to about 12 ounces total quantity. It seems wise to feed smaller amounts than usual and at four-hour intervals under such circumstances. The cream is omitted because it is probably the hardest of the various food elements to digest, and we believe is the last to leave the stomach. It has been demonstrated that the stomach of the child can grasp the thick cereal feeding much better than it can the thinner used formulae and that vomiting will not be as severe. This formula, combined with atropine or phenobarbital in proper doses, will give you a starting method of handling the child who is vomiting and in whom you suspect some pyloric obstruction. It is well to remember that a vomiting child is usually in a state of water deficiency. The administration of normal saline solution subcutaneously is very advantageous in the handling of these cases.

In Table 11 a formula for feeding the malnourished child

TABLE 11

FEEDING THE MALNOURISHED CHILD

Based on expected—not the actual weight) four months old weighing 8 pounds

		Calories.
Whole milk . . . . .	24 ounces	$\times 20 = 480$
Lactose . . . . .	4 level tablespoonfuls	$\times 40 = 160$
		<u>8)640</u>
Bottle water . . . . .	6 ounces.	
Inf. oil . . . . .	48 drops.	80
5 bottles of 6 ounces each—Feed every four hours.		

is given. The formula is based on the expected rather than the actual weight of the child. The case in question is a four-month-old child weighing 8 pounds. The expected weight of such a child would be about 14 pounds. In such circumstances lactic acid whole milk with added lactose is used. When based on the actual weight it is noted that this child receives 80 calories per pound, but when based on the expected weight of 14 pounds it amounts to about 45 calories per pound. The lactic acid is used in this formula because so many of the malnourished infants have an insufficient quantity of acid in their stomachs. This aids materially in making the formula more digestible. In feeding the malnourished, the formula is not the entire problem in all the cases. In some the reason for the malnutrition may be found if a careful examination of the child is made. Chronic diseases such as tuberculosis and syphilis must be ruled out as etiologic agents. Some acute infections of the upper respiratory tract, the urinary tract, and the gastro-intestinal tract must be searched for. Quite a large number of malnourished children are in such a condition because of some congenital anomaly of the heart or some other vital organ. If your child does not progress on the above formula, do not blame the formula but look for the specific cause for the malnutrition.

In feeding the acutely sick infant, a few very important facts should be kept in mind. The appetite has been lost, its digestive capacity lessened, the digestive enzymes are less in amount and less active. It is wise to remove cream from the milk that is used. The amount of sugar should be reduced. If possible, maintain the required fluid intake. If the nose is obstructed by congestion, it is wise to feed by spoon or a medicine dropper. As soon as an infant becomes ill these general principles should be put into effect.

In Table 12 some general principles are given for feeding the child who has *diarrhea*. A *starvation period* should be given the infant of from six to twenty-four hours, but no longer, except in unusual circumstances. During the starvation period, fluids such as water, barley water, weak tea, and fruit juices should be given, trying to keep the fluid intake up to or slightly above normal. A good starting formula for such an infant consists of skimmed milk and barley water, equal

TABLE 12

## FEEDING THE CHILD WHO HAS DIARRHEA

Starvation period.....	Six to twenty-four hours—no longer.						
Fluids during starvation—	Water, barley water, weak tea and fruit juices.						
Starting formula.....	<table> <tr> <td>{ Skimmed milk.....</td><td>12 ounces.</td></tr> <tr> <td>{ Barley water.....</td><td>12 ounces.</td></tr> <tr> <td>{ Dextrimaltose.....</td><td>1 tablespoonful</td></tr> </table>	{ Skimmed milk.....	12 ounces.	{ Barley water.....	12 ounces.	{ Dextrimaltose.....	1 tablespoonful
{ Skimmed milk.....	12 ounces.						
{ Barley water.....	12 ounces.						
{ Dextrimaltose.....	1 tablespoonful						
6 bottles of 4 ounces—	feed every four hours.						

parts, with a small amount of dextrimaltose. This formula should be continued for several days, waiting for favorable signs before increasing its strength. The favorable signs are decreased frequency in the number of stools, and a tendency to become more formed. As soon as such signs are present the formula may be increased in strength, gradually adding cream and increasing the carbohydrate.

Associated with diarrhea is another condition which we are so apt to forget, namely, a change in the water balance and acid-alkali relationship. These changes are most important and demand early recognition and prompt treatment, otherwise fatalities may occur. There was a time in the history of infant feeding when diarrhea associated with a toxemia could destroy a child in a twenty-four-hour period. It was spoken of as "milk poisoning." We believe now that it is more than likely due to chemical changes that have taken place in the body. This chemical change is spoken of as "acidosis."

In acidosis the pH of the blood is below the normal of 7.35 to 7.45. The neutral hydrogen ion concentration gives a pH of 7. Anything below that is on the acidotic side and anything above that is on the alkalitic side. Another way of determining changes in the electrolytic balance is the estimation of the CO<sub>2</sub> combining power of the blood. Normally this is from 40 to 60 volumes per cent. An alkalosis is anything above 60 volumes per cent, and an acidosis is anything below 40 volumes per cent. The blood is slightly alkaline at a constant level, although acids are being formed all the time. The acids are neutralized by the excess of base, including carbonates, phosphates and proteins, or some is lost by the lungs as CO<sub>2</sub> in the expired air; the kidneys are able to secrete organic and mineral acids and also have the ability to break up urea, so liberating ammonia, which will help to neutralize

excess acids formed in the body. By these various mechanisms the body is able to maintain the blood at a constant level of slight alkalinity. In the presence of diarrhea and certain other diseases these normal methods of neutralization are insufficient to make proper adjustments. In diarrhea there is an excess loss of base from the body when large amounts of digestive juices are secreted to overcome the diarrhea. In diabetes and starvation there is an abnormal production of acids in the body. In extensive pulmonary disease proper elimination of  $\text{CO}_2$  is interfered with. In nephritis the kidney is unable to perform its proper functions of elimination or neutralization of acids. It is by paying particular attention to these features that cases of diarrhea can be easily managed. In some of the cases of acidosis associated with diarrhea and other conditions, the mucous membranes of the mouth have a cherry red color. An acetone odor to the breath may be noted. There is nearly always hyperpnea, the respiration sometimes reaching 80 to 100 per minute. The skin has lost its elasticity and when pulled up in a fold is very slow returning to its normal state. This is spoken of as "dehydration of the tissues." Even though the body has a large storehouse of fluids in reserve in the various tissue spaces, a profuse diarrhea and especially if associated with vomiting, will drain this reserve in a very short time. This must be replenished promptly or a fatality may result. The treatment consists of giving normal saline and 10 per cent dextrose by mouth, by rectum, by vein, or into the peritoneal cavity. Normal saline solution or Hartmann's solution subcutaneously is very advantageous.

In Table 13 an outline is given for vitamin feeding. Whether a child is breast-fed or bottle-fed, these vitamins should start at one month of age. It is wise to begin orange juice with small amounts well diluted in water, and increase as rapidly as possible so that the child is getting at least 2 ounces of orange juice by the time it is three months of age. Cod liver oil, supplying vitamins A and D, should be started in small amounts, preferably from a dropper or spoon, and increasing slowly so that the infant gets 3 teaspoonfuls of cod liver oil by the time it is five or six months of age. Sunshine, not necessarily direct, should be secured for the infant. Two to four hours daily in the open air should be part of the reg-

TABLE 13  
VITAMIN FEEDING

Orange juice At 1 month—Vitamin C—1 teaspoonful to 2 ounces.  
Cod liver oil At 1 month—Vitamins A and D—10 drops to 3 teaspoonfuls  
Sunshine... Two to four hours daily.

## Additional Foods

- At 4 months start vegetables.
- At 5 months start cereals.
- At 6 months start egg yolk.
- At 7 months start fruit pulp.
- At 8 months start puddings.
- At 9 months start zwieback.
- At 10 months start egg white.
- At 11 months start meat.

imen for each infant. Additional food, such as vegetables, cereals, egg yolk, fruit pulp, puddings, zwieback, egg white and meat, may be started approximately as indicated in Table 13. The beginning of these additional foods will depend on the circumstances of the individual case. They may vary, depending on the needs. In case of constipation, fruit pulp may be started first. In case of developing anemia, the iron-bearing foods or vegetables, and preferably pabulum, may be started first. As soon as teeth appear, some hard substances, as crust of bread or dry toast or crisp bacon, should be instituted. The child should be taught to chew as soon as possible. It is always wise, in feeding these additional foods, to begin with extremely small amounts, increasing as tolerance is developed. The mother should be cautioned not to be annoyed or disconcerted if the infant first refuses these additional foods. Constant repetition of these feedings by an unemotional mother is bound to correct the difficulty in a relatively short time. The canned commercial vegetables seem to be well adapted for infant feeding.

In Table 14 are listed the types of stools that may be expected in the infant. It is well to have a clear understanding of these stools, and it is particularly well to remember that there is a close analogy between the starvation stool and meconium, and to remember that the starvation stool is not an indication for further reduction of the formula as one would in diarrhea, but is a clear indication for an increase in the

TABLE 14

## TYPES OF STOOL EXPECTED

Meconium.....	Brown, tarry, during first three days.
Transition.....	From third to sixth day, mucus, brownish-yellow curdy.
On breast milk...	Liquid, yellowish—acid, 1 to 5 daily.
On cow's milk...	Formed, yellowish, putty—alkaline, 1 or 2 daily.
Additional foods.	Colored by vegetable used.
Starvation stool.	Greenish, loose, mucus, 2 to 5 daily.

amount of food, if the general situation is satisfactory. It is well to remember that the transition stool, which occurs on the third to the sixth day of life, is a sign of gastro-intestinal irritation and in many cases of inflammation. It is during this period that breast feeding is indispensable, but in case of artificial feeding a diluted formula is advisable.

The first year of life should be a period of training for the child. It should learn how to suck from the breast, to suck from a bottle, to eat from a spoon, to drink from a glass, to chew hard foods, to like and digest milk, cereals, vegetables, eggs, meats, fruit juices, and cod liver oil, without coaxing, urging, or entertainment during mealtime.

## CLINIC OF DR. PHILIP S. BARBA

### GERMANTOWN DISPENSARY AND HOSPITAL

---

#### UNDERNUTRITION IN CHILDREN

IN the later conception of undernutrition in children we find many changes from the ideas even of fifteen or twenty years ago. Pediatricians are swinging away from the hard and fast rules of height-weight tables. Even the more recent tables of sitting height and of shoulder width and hip width-height ratios are tempered by consideration of the individual and of his family characteristics.

Certainly we are no longer concerned with weight alone. Any survey of an individual's state of nutrition must include: the rate of growth, the firmness of the muscles, the posture, presence or absence of anemia, the ability to maintain physical and mental effort, the degree of nervous fatigue as indicated by nervous irritability, whining, easy crying, etc., the individual's resistance to infection, and dental caries.

In other words there is no one measure of the state of nutrition when considered in the broad sense. We must take the complete picture. I do not mean that a child who shows only one of the above-mentioned criteria is suffering from undernutrition, but a child showing a fair proportion of them is undernourished.

In the practice of medicine our problems are how to correct the condition and how to prevent its occurrence.

Undernutrition is rarely, if ever, a primary condition. There is always some underlying factor, although in many cases it is impossible to uncover the actual cause and we are limited to symptomatic treatment.

Under etiology we can place a long list of conditions, most of which are subdivisions of the following:

Diet.

Infections.

Anemia.

Psychic or neurologic disturbances.

Endocrine disturbances.

Heredity.

It is impossible in an article of this scope to follow out all the ramifications of the various etiologic factors. Moreover, it is our wish to be of practical help in this problem, so we will confine the discussion to the boundary of practical medicine and of common sense.

Let us remember, when considering the question of diet, that we are concerned not only with what goes into the child but with what becomes of the ingested foodstuffs.

Here again we are confronted with the variation of the individual. A 1928 automobile can be driven quite successfully with a low-price gasoline which would give very poor results in a modern high-compression motor.

So it is with our diets in nutrition problems. One child can absorb and utilize one type of food readily, another gets no benefit from that food. One child needs to be fed small amounts frequently, another needs to cut out his between-meals snacks. There is no rule. These questions must be worked out for each individual.

We can further extend our comparison to the automobile. If a car is run at high speed there is a greater demand for fuel, lubrication and water. So with humans, the individual putting out great effort, either nervous or physical, requires a greater energy intake than one at rest. Furthermore, the problem is complicated by the question of nervous fatigue causing anorexia or faulty digestion and metabolism. It does no good to push food into an exhausted child who cannot digest it or can absorb it only poorly.

It is evident, then, that faced with a case of undernutrition we must study that case as an individual. As a practicing, and I like to think practical, physician, I am overcome with envy when I read the works of some authors, and see the painstaking and detailed studies they have made on some of their cases. We are usually confronted with a case requiring study, or one which would be interesting to study, but the

family have no financial ability and often no desire to undergo such protracted efforts to arrive at the truth. In practice such cases come into one's office with a finally anxious mother in search of a "tonic" that will put on pounds in a few days. I wish to heaven it were as simple as they think, and as some of the detail men from commercial houses would have us believe. If we believed the claims some of them put out you could expect to anoint your hardwood desk chair with their preparation and have it turn into an overstuffed sofa. Unfortunately the road to good nutrition is too often as hard to traverse as the road to knowledge.

When these cases come into your office you have to start with a complete history—the individual's history starting with its term *in utero*, and the family history going back, as usual, two or maybe three generations.

Was the delivery normal, protracted, precipitate, instrumental? Was the neonatal period normal or complicated? What was the early feeding history, the condition of the bowel? The type of eating habits? What were the illnesses of infancy and childhood? Did any psychic factors develop? Any growing pains or other possible indication of latent rheumatic infection? Were any allergic symptoms manifested? Did any acute or apparently minor illness occur before the onset of the undernourished condition? Have respiratory infections been common? Has the child showed any signs of parasitic infestation? What type of appetite does the patient have? Is he hungry but quickly filled? Will he eat large amounts of things he likes? Does he eat between meals? Are his stools light-colored or soapy? Are they sour and fermentative? Are they constipated because of low intake or is the intake low because he is constipated? Is he gassy? Are the stools putrefactive? Is the child whining, crying easily, quickly exhausted? Does he feel better after eating? Which meal does he eat best? What methods have been previously used to quicken his appetite or to improve his nutrition? What has the growth and development curve done in previous years?

In the family history we must look for hereditary characteristics of growth, for allergic diathesis, for rheumatic tendencies, tuberculous contacts, endocrine disturbances, anemias, etc.

The social history should include the home and school environment, the family attitude, the sleeping conditions and the general hygiene.

Following the history comes a thorough physical examination. This should start with a general summary of the physique. Is the stature short, the bones small, are the legs, arms and trunk in proportion? Any craniotabes? Or evidence of rickets? How is the posture? What is the tone of the muscles? Any skin conditions? Any gross evidence of endocrine disturbance? Have the child lie flat and see if the abdomen is scaphoid in that position. Can he sit up from the recumbent position without help? Is there a diastasis of the recti? Any hernias? What about the secondary sex characteristics? Any sign of goiter or of myxedema? Make a careful examination of the nose and throat, and be suspicious of sinus infection when you see overgrowth of lymphatic tissue on the pharynx. Abscessed deciduous teeth may be a cause of anorexia, and loss of chewing teeth has been given as a cause for improper absorption of food. A low-grade gingivitis may explain a lack of appetite and of course the tonsils should be given a very suspicious inspection. Halitosis, so prominent in the advertisements of late, may be a result of postnasal drip from a low-grade ethmoiditis, from tonsillitis or may come from digestive disturbances with faulty gastric secretions. Cervical nodes may be a clue to a focus of infection and a suspicious thyroid with a rapid pulse may indicate a more serious condition.

The chest may be negative to the ear and to the percussing finger but in the face of failure to produce results after reasonable treatment or in the absence of other clues a tuberculin test and an x-ray are warranted. The abdomen may show visible peristalsis or palpable masses. It may be distended and tympanitic or flat and dull with a spastic cecum or sigmoid indicating an irritated bowel. You may be able to localize a point of tenderness in the right lower quadrant or lumbar region indicating a low-grade appendicitis. Nicholson<sup>1</sup> has reported a series of cases of mechanical lesions of the appendix, some of which showed remarkable improvement in nutrition after appendectomy. There may be significant

herniae. Sometimes the correction of flatfoot brings about remarkable changes in disposition and appetite.

Suppose our physical examination reveals nothing of significance, what more can we do, or what are we justified in doing, in the way of laboratory work? All cases should have a routine urine examination and most should have a blood count. A chest x-ray should be held in mind as should a stool examination. Both of these are important, but where expense is a factor can be held in reserve until the results of preliminary treatment have been observed. These cases require such a detailed history and physical examination because their etiology is so obscure, and because the younger children at least cannot give us accurate subjective symptoms.

When starting treatment on these cases I feel we should always take the parents into our confidence. Outline what we have found wrong and what we intend to do about it. If they are the worrying kind and feel that reassurance is worth the expense it is wise to have the various fundamental laboratory work done at once. As I stated before, I think all of these children should have a urinalysis and practically all should have a blood count. x-Rays can well be reserved unless the parents feel it essential. Personally I think an x-ray of the chest is the most important as it may give information not attainable by the ordinary physical examination. Gastrointestinal x-rays rarely give much information. Occasionally they will pick up a previously unsuspected megalocolon or redundancy of the bowel. After all, such things make little difference in the treatment. Even a latent tuberculosis in childhood would be treated exactly as we treat all malnutrition. A Mantoux is less expensive and in the younger children more definite than x-ray in diagnosis.

Where infection exists we must of course do everything possible to eradicate the focus. In my experience the most common focus is in the sinuses. As we all know, only too well, treatment of chronic sinusitis is disappointing. However, it must be remembered that infection and undernutrition set up a vicious circle which must be continuously and patiently treated from all angles.

Here again I wish to emphasize the factor of energy expenditure. We have all seen children with a good energy in-

take and failure to gain when infection is present. We may take this as definite evidence of the energy required to combat the infection, or lost because of the presence of infection. All parents complain when told the children must rest. Most of them will cooperate when the need is described in simple terms of energy intake and demand. The easiest is the analogy to a furnace with the drafts on and the windows of the house open. I put one patient to bed for three months. In two years she had failed to gain past 42 pounds. The first three weeks she gained very little, after that she gained steadily until she had put on 20 pounds.

Much has been written recently of the various elements of the diet. One can find almost any theory to have worked in the hands of various people. The chemical constituents and the vitamins have been much in prominence during the last few years.

Marriott, Jeans and Clausen<sup>2</sup> give an excellent brief discussion of the various chemical and vitamin factors. Marriott feels that the average diet contains sufficient amounts of sodium, potassium, magnesium, sulfur and chlorine. Calcium, phosphorus, iron and iodine may be deficient.

Jeans feels that too much iron added to the diet may be harmful and might even cause low phosphorus rickets. As a satisfactory dose he cites 5 mg. a day for children three to six months of age and 10 mg. for children six to twelve months of age. He points out that the much-vaunted spinach supplies little iron and that in large quantities may even rob the body of iron. Jeans also points out that the celiac diet, high in proteins and monosaccharide sugars and low in fats, frequently works wonderfully well in undernourished children not really in the celiac class. He feels that such a diet is more apt to increase weight than the small bulk, high fat diets which often are less readily utilized by the child.

Glassburg<sup>3</sup> puts his trust in urging the individual to greater caloric intake, making the diets as varied and attractive as possible. Most of his work was done with adults. He found a vitamin B concentrate fairly effective.

McCallum<sup>4</sup> feels that we are on the edge of still greater discoveries in the nutrition field. He quotes Rose of the University of Illinois as authority for saying that of the 22 known

amino-acids 9 are essential in the diet, 9 not essential and 4 are not yet sufficiently studied.

Clausen<sup>2</sup> cites the recent developments in work with vitamins. He feels that earlier administration of vitamins may prevent later hypovitaminosis.

Holt<sup>5</sup> and fellow workers have done an exhaustive piece of work on fat absorption. I was interested to see that they found a high mineral intake gave a lowered fat absorption. These workers also felt that atrophic infants were not able to absorb fat normally.

My personal feeling is that with a little effort and thought most, if not all individuals, can be given an adequate diet. I have found that most of my cases do better with a low fat diet. Many cases I have taken entirely off fat for a period and increased the protein and carbohydrate elements, using vitamin concentrates to supplement the diet. I feel that such a diet should not be continued over too long a period, as some of the unsaturated fatty acids seem to be essential elements of the diet. (Burr and Evans.<sup>6</sup>)

Some children with poor appetites will gulp down a glass or two of milk and eat practically nothing else. In such cases I feel we should take milk entirely out of the diet. The child's mother usually exclaims in horror that he will certainly starve. However, if we give meat twice a day and egg once a day with fair helpings of vegetables, throw in some calcium and keep up the liquid intake, after about a week their appetite for the general diet is markedly improved. Temporarily cereal may be given twice daily, but as a general rule I prefer only one cereal feeding when the child is on full diet. Such cases, if they do not actually lose weight, I will keep off milk a month or more and then add it in minimal amounts, usually 1 to 1½ pints a day. Frequently I attempt to aid digestion by using hydrochloric acid and possibly pepsin or caroid at mealtimes. I rarely use tonics of the usual strychnine variety. I feel that they stimulate the individual to greater activity and most of these children need to be held down rather than stimulated. In spite of my preference for low fat diets I have, in some cases, seen decided gain in weight where fat is added to the diet. This may be done with cod liver oil, but many of the older children hate it and are nauseated by it when given in

doses large enough to be of caloric value. I have had better luck with olive oil and corn oil. The latter possesses the advantage of being rich in unsaturated fats, and, according to Holt *et al.*,<sup>5</sup> the unsaturated fats seem to aid absorption of all the fats in the diet.

Where pronounced anemia is present and fails to respond to rest, diet, medication, etc., I feel that small transfusions should be used. This is rarely necessary except when infection is present or following severe infections.

The psychic factors are often discouraging to treat. "You can't teach an old dog new tricks" is an old and trite saying but it certainly applies to some of the anxious and neurotic mothers one meets in these cases. With older children school during the winter and camps in the summer will help in some cases. I once lost a friend and patient by telling such a mother her child would be all right when he was old enough to get away from her, but I was proved right. In younger children I have occasionally been driven to putting the child in foster home or convalescent home until the psychic element could be broken down. In nervous, highstrung children correction of minor eye defects is often of value.

The inherited types are possibly the most difficult. It may be due to a fault in the germ plasm. Possibly we would not be confronted with such cases if medical science had not developed ways of saving many of these infants. It may be that some of them are endocrine in origin. I have seen a few decidedly benefited by thyroid medication. We can be helped in this diagnosis by x-ray of the wrists and hands for the centers of ossification. Thyroid should be started in small doses,  $\frac{1}{10}$  grain, and worked up slowly.

Much has been written about the use of insulin in under-nutrition. Pitfield<sup>7</sup> originated this method and in his hands I have seen good results. Many writers have come out against it and many have found it of help. Ellenburg<sup>8</sup> recently reported its use in 10 cases. He felt that there was no remarkable gain in weight but a very definite change for the better in the general vitality and behavior of the children. Where insulin is to be used the child should be hospitalized.

Apparently most of the endocrinologists feel that the growth hormones, etc., are not yet sufficiently studied to be

useful in general work. I have had no personal experience with them, feeling that, as yet, such work is too experimental. Undoubtedly the time will come when we will be equipped with a potent weapon for use in the children showing a symmetrical but undersize physique and a small capacity for food.

In closing there are a few points I want to stress.

Rest, enforced if necessary, is an essential part of any treatment of undernutrition. With children rest is almost impossible unless they are kept occupied with games or other amusements. With a little ingenuity, much can be done to keep a child happy in bed. A bowl of puffed rice and a box of toothpicks can be made into interesting animals, houses, trees, etc. A platter or tray of corn meal will take the place of sand. Reading hours, erector sets, etc., can all be utilized for restful amusements.

Belts and braces for the correction of ptosis are usually disappointing. In any event they should be combined with exercises to strengthen the muscles they are designed to support.

Nutrition is difficult to maintain in the presence of infection, and infection is difficult to eradicate in the presence of undernutrition. The two are very apt to be found together so both must be treated.

Tonics may be used but must not be abused. You can whip a tired horse all day and he can't go any faster.

## CLINIC OF DR. P. S. PELOUZE

UNIVERSITY OF PENNSYLVANIA

### PSYCHOGENIC SENSORY AND FUNCTIONAL UROGENITAL SYMPTOMS

THE extent to which the mind plays a part in the development or continuation of sensory and functional symptoms of the urogenital tract is not realized even by one who devotes years to urologic study. For no sooner does he get the idea that he at last has become really conversant with the matter than an entirely new and previously unsuspected field opens to him.

It is probable that no organs or functions of the human body are more dependent upon a proper psychoneural balance than are those of the lower urogenital tract. Even urination, that one starts almost at birth and periodically continues throughout life, never escapes psychic meddling in a large percentage of individuals. Nor can one say that these individuals are psychoneurotics. If they are, then at least 50 per cent of all males are to be classified thus. For that is about the percentage that finds it impossible, or almost so, to urinate in the physician's presence. Just so soon as he leaves the room and closes the door, the trick is turned. Singularly enough, the older the physician grows the more journeys he must make from the room. Assuredly, there is something in gray hair that starts urination-inhibiting impulses in patients.

Unfortunately our search in psychic fields does not stop with that vast horde of urinary hesitators. It reaches far into functional avenues, it covers a larger part of sensory disturbances than any of us suspect and, when it comes to the matter of sex, it almost occupies the entire picture. Often it must work from gross pathologic and structural change to underlying and causal mental fixations. Even more often our search

carries us from fixed or fleeting sensory symptoms to their causes in the mind, things that may have been the children of fears or merely the discomfort memories of former pains that should have died with the removal of the cause.

For time out of mind we have called the outstanding members of these great groups "urogenital" or "sexual neurotics." Usually we did not pause to consider the reasons why they were as they were. They pursued their seemingly endless journeys from doctor to doctor with scant comfort and usually less relief, many of them still do. During those journeys they met little that had to do with a study of what was happening in the mind but an almost endless train of instrumental procedures that served only to deepen the mental scar that made them medical nomads.

As urology has delved more and more into the diagnostic art it has narrowed greatly the range of the so-called "idiopathic." It has found the reasons for a large number of conditions and has developed treatments appropriate to them. It, however, has missed to a great extent the tricks the mind can do and often does in symptom creation in this portion of the anatomy.

Let us consider first that matter of psychogenic sensory symptoms, mentioning at the beginning a very frequent evidence of the fact that there are such things. The patient, usually a married man, presents himself with the statement that he strayed from conjugal paths, thinks he has contracted gonorrhea and has a burning pain at about  $\frac{1}{2}$  inch from the external urinary meatus. The sensation came immediately after he got the idea of infection and has remained. The doctor takes a smear from his urethral secretion, stains and studies it microscopically in the patient's presence, finds nothing, and insists he has no gonococcal infection. Before the patient leaves the office he remarks in wonderment that the pain has disappeared entirely. And it fails to return unless he again gets the fear he has been infected.

Of course the mind more often generates sensory symptoms in the bladder than in any other portion of the tract, and this fact accounts for a great number of cases in which no local cause can be found. As such sensory discomforts center preponderantly in the trigone they naturally go a step further

and disturb urinary function, with frequency of urination as an outstanding feature. Continued over any great length of time, the not infrequent result is change in structure, as will be seen later.

Our commonest form in this group is born of the fear that the bladder will be injured if it is made to hold a large quantity of urine. Most of these mental fixations formerly were found in youth and early adolescence, but of late years the rather widespread fear of prostatic hypertrophy in the male and bladder malignancy in the female has shifted the statistical balance so that the palm may belong to those beyond middle life. The sequence of events runs about as follows: the fear is born and grows, the mind analyzes urinary function to the extent of becoming bladder conscious, trigonal sensitiveness is the next step, and then a constant and seemingly mysterious frequency of urination sets in. It might be of interest to cite several cases.

R. J., age twenty-four; while attending a party at eighteen years of age, had the desire to urinate but, things not being propitious, he delayed it until about two hours later. He had a little difficulty in starting his urinary stream, which he noticed was quite small after the first portion of urine had been passed and, toward the end of urination, it just flowed out without any projectile force, as it naturally would under the circumstances. Being sure he had injured his bladder, he decided to rest it by not allowing it to fill for a few days. By the end of this time he found he developed a trigonal discomfort when the bladder contained but a small quantity of urine. Within a month he was urinating at about half-hour intervals day and night. His father took him to doctor after doctor and, in the absence of findings satisfying to the medical talent, he finally was said to have diabetes insipidus. He was given various glandular products and denied fluids almost to the point of dehydration.

If the doctors had taken the trouble to measure the amount of urine passed at each urination, as well as his twenty-four-hour output, a little arithmetic would have thrown the question of diabetes insipidus into the discard, also five years of treatment would have been avoided.

A careful study proved that the only things wrong with

the patient were an assortment of mental fixations and a bladder of small capacity simply because it had not been stretched for years. Revealing these fixations to him and self-retraining of the bladder brought surprisingly quick cure.

Mrs. F. K., age forty-seven; complained of "pain coming on five minutes after urination and lasting for hours." She had a normal urine, normal bladder and urethra and no apparent pelvic disorder.

She had a neighbor dying of vesical carcinoma who had the same symptom. Her own pain stopped immediately after she was assured nothing was wrong with her bladder.

J. W., age sixty-eight; had been in bed for two weeks complaining of marked discomfort at the base of the bladder with suprapubic transference and was urinating every few moments. He had a self-made diagnosis of prostatic hypertrophy and had convinced his physician that such was the case. The latter was under the impression that, despite his inability to map out a distended bladder, the frequency was practically the overflow of retention.

Examination and later cystoscopy failed to reveal anything abnormal. Questioning elicited the fact that he had two friends with prostatic hypertrophy and that he knew more about the symptoms than a doctor was likely to know after years of observation of such patients. He was cured within a half hour of the time he was assured that there was no prostatic obstruction and the only reason for his frequency was the fears he had built up.

The question of deranged urinary function, aside from that secondary to trigonal discomfort born of mental concentrations, is an interesting and decidedly important one. Some of these cases may start in infancy as the result of a pinpoint urethral or preputial meatus and continue for life, though the initial obstruction has been removed. Others develop the pernicious urinary habit during youth as the result of ideas, perhaps, in such an experience as outlined in the first case cited. The outcome of both is the habit of making urination a matter of straining to force the urine out rather than one of normal sphincter relaxation. In the mind there is the conviction of obstruction to urination, as a rule. The patient refuses to stand and wait for relaxation, which his mental inhibitions

make more and more difficult, but takes what, to him, is the time-saving method of helping out with his abdominal muscles.

Of all urinary habits this writes the most easily readable of cystoscopic pictures, for the bladders of such patients show all grades of trabeculation. Early the picture is suggestive of *tabes dorsalis* except that there is spasm instead of relaxation of the vesical outlet. After years of the practice the bladder would do justice to a chronic prostatic obstruction, except that there is no obstruction. Nor is there vesical outlet relaxation to suggest *tabes*. Instead of stretching, as one might expect, the bladder grows smaller because of the great hypertrophy of muscle fasciculi and the patient has to arise at night. Owing to this he consults the physician, who naturally assumes from the history of difficult urination, which the patient forgets has been present for years, and the nocturia, that lower tract obstruction is present and some time later he reaches the cystoscopic table.

Some really do develop a prostatic obstruction, get a suprapubic prostatectomy and the wound leaks for weeks or months because they still strain to start the urinary stream. Cure depends upon the removal of the fixation and the correction of the urinary habit.

Then there is that rather large group of patients of uneasy conscience and good sensation memory who persist in having urethral, perineal or rectal pains or discomforts long after the reasons for them have gone. In the distant background is a severe gonococcal infection for the treatment of which much traumatic urethral instrumentation has been carried out. In the ever-present and immediate background is the conviction that something still is wrong. Their idle moments are filled with apprehensions and they find it difficult to get the mind away from the urethra long enough to concentrate on the other needs of life. They think they get temporary benefit from either the passage of a sound or an endoscopic treatment, but before long the symptom returns. The treatments only serve to fix the mental scar.

Finally someone, after a careful study that reveals nothing that locally could serve as a cause, sits down and searches for the mental fixations, opens the patient's eyes to what is going on, gets him to take a two or three months' rest from treatment

and, if the salesmanship is good, produces a cure. Telling any of these patients that it is "all in the head" gets mostly nowhere. They must be shown how and why.

R. S., age thirty-two; had a gonococcal infection with much instrumental treatment twelve years before. He was told he was cured, but because of shreds in his urine he did not believe it. Shortly he developed an uncomfortable sensation along his urethra with an occasional slight twinge of pain. He went to an urologist who impressed him greatly by passing an endoscope and looking for the trouble. Feeling that this gave sensory relief he returned for more treatments and continued to do so for the whole of the intervening time.

A careful study revealed only that the posterior urethral mucosa was quite bluish from the repeated applications of silver nitrate and, because the urologist had not mopped out the overflow silver nitrate solution before withdrawing the endoscope, the bulbar portion of the canal had built up a squamous coating to protect itself.

Further endoscopic treatment was refused and the patient was told what it was all about. The salesmanship was not convincing for he returned to the other urologist for eighteen months more of endoscopic applications. He then returned, agreed to go three months without treatment, kept the promise for a month and then contracted gonorrhea. This did not pass to the posterior urethra, but he knew endoscopic treatments should not be done while he had gonorrhea. When the gonorrhea was gone the urethral discomfort and pains were gone also and they failed to return. At least, we can score one in favor of gonorrhea.

It would be a simple matter to cite a large variety and a large number of cases wherein the erasure of mental fixations, following a most careful urogenital study, were the only means used in the eradication of both sensory and functional symptoms. The danger is that one not skilled in such studies will overlook true causal pathology. One makes no mistake, however, in the presence of minor changes of function or mild sensory symptoms, particularly if the urine is normal, to go rather carefully into what the patient is thinking about his troubles. Usually it is a simple matter to find the true underlying fears and fixations that will explain much that otherwise

seems obscure. Particularly does this apply to the urinary functional disturbances before the age of thirty-five years. In later life there more often is easily demonstrated pathology to explain such dysfunction and it is only after the proof that such pathology does not exist that blame should be shifted to the mental sphere. Of course, this applies to the earlier age groups as well.

When one turns to the various departures from what we have been pleased to call "normal sex function" he finds himself in a psychologic sea. So much of it has to do with what a man thinks that the physician soon finds himself relegating endocrine urge to a comfortable but almost forgotten seat in the back row. If he looks to the mind for the explanation of all of the cases that consult him for impotence and premature ejaculation he will make few, if any, mistakes.

The urethral lesions so commonly said to produce these disquieting experiences are found about ten times as often in the blood brothers of Don Juan than in those who stumble and fall this side of their shrine. But even these soul-sick brothers, who greatly need a friend, must get an urogenital study if one would break the tie that binds the psyche to their fallen hero. Nowhere in the entire realm of psychogenic projections is it more needful that the sorrowing one be immovably convinced that his doctor knows what he is talking about. In no other way can he surely be readjusted to his opportunities.

## CLINIC OF DR. CLIFFORD B. LULL

PHILADELPHIA LYING-IN HOSPITAL

---

### THE DIAGNOSIS AND TREATMENT OF THE ANEMIAS OF PREGNANCY

**Case History.**—The patient presented this morning is suffering from a condition which is a rather infrequent and serious complication of the pregnant state. Her family history is negative. Her personal history is negative except for an attack of rheumatic fever during adolescence. This is her third pregnancy, the last being five years ago, both the earlier ones having been spontaneous and without history of toxemia or complications during pregnancy or the puerperal period. She was referred to the hospital by her family physician with the diagnosis of toxemia of pregnancy, and entered the hospital complaining of swelling of the ankles, dyspnea, palpitation and exhaustion.

**Physical Examination.**—Physical examination on admission shows a very marked pallor to the skin and mucous membranes which she has noted for at least two months. She is thin, pale, anxious, and depressed. The neck veins are prominent and pulsating. The left lobe of the thyroid is slightly enlarged. The lungs are clear. The heart is rapid, the rhythm regular, there is slight enlargement to the left, and there is a suggestion of a blowing murmur over the mitral area. The umbilicus is enlarged to the umbilicus, which would correspond to the cessation of menstruation, is rather soft, and there are no tenderness. The liver cannot be definitely outlined. There is some pitting edema.

**Laboratory Report.** On admission, urine showed a faint trace of albumin with 25 to 50 white blood cells to a high

power field. The hemoglobin was 22 per cent, 1,160,000 red blood cells, 7700 white blood cells; 79 per cent polymorphonuclear leukocytes, 20 per cent lymphocytes, 1 per cent monocytes. There was poikilocytosis and macrocytosis. Reticulocytes, 0.4 per cent. Volume index equals 1; saturation index equals 1.

*Blood Chemistry.*—Serum albumin, 3.58 per cent, serum globulin, 1.94 per cent, blood urea nitrogen, 11.2. Takata-Ara test negative. Blood Wassermann negative. Gastric analysis shows almost absence of free hydrochloric and positive benzidine reaction. Microscopic gastric analysis shows many white blood cells, and few epithelial cells. Electrocardiogram shows evidence of some myocardial damage.

*Progress.*—This patient has been under observation for a period of eight weeks, during which time there has been a definite improvement in her general condition, and the blood count has shown steady improvement, so that at the present time the hemoglobin is 51.2 per cent, 2,760,000 red blood cells. Of 1000 cells counted, there were no reticulocytes seen. The pulse and temperature, which were elevated on admission, have subsided to about average.

*Treatment.*—On admission this patient was given the usual routine care, plus the administration of feosol, 6 grains t. i. d., and 1 ampule of Lilly's extract of fresh liver, t. i. d. After observation for several days, with no signs of improvement, it was thought advisable, after consultation with the medical department, to give repeated small blood transfusions. Eight of these transfusions were given in conjunction with the iron and liver medication, during which time some definite improvement was shown. Inasmuch as the question arose as to the advisability of an interruption of the pregnancy, treatment was discontinued for a week. During this time there was a marked reduction in both hemoglobin and red cells, with an increase in reticulocytes. Transfusions were again resorted to, and steady improvement has followed.

*Diagnosis.*—This patient has a severe anemia of pregnancy bordering on the pernicious type.

*Prognosis.*—The prognosis, as far as the patient is concerned, is favorable. The prognosis, as far as the continuation of the pregnancy is concerned, is unfavorable. In all

probability this patient cannot be carried through to full term, and if the uterus is emptied, either spontaneously or by intervention, she should show continued improvement as far as her anemia is concerned.

**General Discussion.**—During the past few years the question of the various anemias that occur during the pregnant state have been repeatedly brought to our attention. The simplest classification of this condition is probably: (1) simple anemia, (2) severe anemia, and (3) severe anemia of the pernicious type.

**Simple Anemia.**—Many observers believe that all women have a moderate anemia during pregnancy which is possibly physiologic. This is a mooted question, however, as the chances are most people at some time of the year have a reduction in both hemoglobin and red cells. It has been repeatedly stated that the simple anemia is the result of increased blood volume. The most important cause, however, is probably insufficient diet. Second to this are gastro-intestinal disturbances that occur during pregnancy, particularly if there is a reduction of free hydrochloric acid and total acid in the gastric secretion. The occurrence of any of the acute infections, as la grippe, pyelitis, and other intercurrent infections, will almost invariably cause an anemia which is already established to become worse during pregnancy. Many of these simple anemias are unrecognized, particularly if the hemoglobin is not reduced below 75 per cent and the red cells not below 3,000,000. As a rule, these patients do not complain of unusual symptoms, and unless one routinely observes the blood count they are oftentimes unrecognized. Occasionally the patient will complain of some lassitude, slight dyspnea, and some pretibial edema. This is particularly true in a patient who already has a slight anemia, who becomes pregnant, and who during her pregnancy suffers from some acute mild infection. The treatment of simple anemia consists first in diet. For many years it has been the custom of many obstetricians to reduce very markedly the protein intake during pregnancy. This is true if the patient shows any slight evidence of toxemia. There are very few cases of kidney involvement during pregnancy who require a nonprotein diet, and if the patient is normal, she should have an adequate amount of protein

during the entire pregnancy. The pregnant woman should have a reasonable amount of protein per kilo of body weight for the development of energy and the stimulation of cellular activity and metabolism. It seems, therefore, that a suitable diet for the average pregnant woman is one that contains moderate protein and is high in vitamin and low in fat. In addition to proper diet, sunlight, if necessary by the ultra-violet rays, is of benefit. Medicinally, the use of iron is probably all that is necessary in this type of anemia, either in the form of Bland's mass or reduced iron. The dose should be rather large, either 60 to 100 grains iron ammonium citrate daily, or 30 to 60 grains of reduced iron daily. In some cases where there is a marked decrease in the hydrochloric acid of the gastric secretion, 15 minims of dilute hydrochloric acid given three times a day, in addition, is of benefit. The use of iron, hypodermically, which was so commonly resorted to in the past, should never be resorted to unless it is impossible for the individual to take iron by mouth. Copper, liver extract and ventriculin have been used with satisfactory results.

**Severe Anemia.**—When the hemoglobin is 45 per cent or less, and the red cells below 3,500,000, the patient is usually suffering from that type of anemia which, according to this classification, would be noted as severe. Most of these cases originated as simple anemias unrecognized until either definite symptoms arose or a study of the blood revealed the true condition present. It is of importance to study the blood of women in pregnancy because, if a slight anemia is found, adequate treatment will prevent its progress to the more severe type. If a reduction of hemoglobin and red cells has been found at any time during the pregnancy, frequent blood counts should be taken to make sure that the blood is maintained at an adequate level during the entire pregnancy. The treatment of the severe type of anemia seen in pregnancy is as discussed previously under the treatment of simple anemia, plus the giving of small blood transfusions. There has been much discussion as to the advisability of transfusions, but if used intelligently, they are of unquestionable therapeutic value. Small transfusions given every two or three days are much more efficacious than massive transfusions, and result in fewer

unfavorable reactions. The usual safeguards as stressed in the giving of any blood transfusion should surround the patient at this time.

**Severe Anemia (Pernicious Type).—**This type of anemia, which is very frequently fatal, fortunately is rather rare. Some authorities estimate the mortality rate as from 60 to 70 per cent. There are many of these that probably are not diagnosed, but are put down as being cardiorenal-vascular disease. There is in this type of anemia a very marked deficiency or total absence of free hydrochloric acid and also a lack of the intrinsic factor of Castle in the gastric secretion. This lack or loss of intrinsic factor, however, is only temporary, while in the addisonian anemia it is permanent. Cord changes are seldom present. The diagnosis is made from a careful study of the blood. The red cells are more greatly reduced than the hemoglobin. The white cells vary, but usually a normal or slightly increased white count is found. The red cells are larger than normal. The volume index is usually greater than 1. The fragility of the red blood cells is normal or reduced. The bleeding time and clotting time are variable. The iron index is normal or greater than normal. The treatment must be active and intelligently administered. Although blood transfusions probably are not used frequently in the very critical patient, a few small blood transfusions will improve the patient, while the administration of liver extract or hog's stomach or autolyzed yeast is given a chance to become effective. The liver extract of either Lilly, Mulford or Valentine's E29 will be found to be efficacious. A careful check of the reticulocyte count should be made at regular intervals of from three to five days. A diet similar to the diet used in the simple and severe anemias of pregnancy is indicated. It is particularly essential that the treatment be continued until the blood count is normal, and even after delivery careful observation should be made to see that no relapse occurs.

**Other Anemias.—**The presentation of this patient has brought up the discussion of the foregoing types of anemia, but your attention is called to the secondary anemias following the various hemorrhages of pregnancy, and the anemias, hemolytic in type, which are a result of postpartum sepsis. In these conditions, frequent small blood transfusions are of

the utmost value. There is reported in the literature an occasional case of splenic anemia, aplastic anemia, and various other blood dyscrasias, which, as in cases other than those in the pregnant, are very frequently fatal. These, fortunately, are not frequent.

The question always arises in a patient who is suffering from a marked anemia, as to whether or not the pregnancy should be interfered with. This is very seldom necessary as the simple and severe types of anemia usually respond to treatment very satisfactorily, and the severe anemia of the pernicious type will usually abort spontaneously. This has been my experience in the few cases that I have seen of this severe or pernicious type of anemia complicating pregnancy. Any patient who suffers from an anemia of any degree during her antenatal period, should be particularly safeguarded against blood loss during delivery or postpartum. These patients also are more liable to infection, and their convalescence, if they have an exhaustive labor, is usually prolonged.

**Summary.**—It is of utmost importance that the blood of the pregnant woman be observed from time to time. An unrecognized or inadequately treated anemia of pregnancy probably plays an important part in the development of many of the complications of pregnancy, labor, and parturition, such as premature birth, dental caries, faulty lactation, delayed involution, postpartum psychosis, and because of lowered resistance, the occurrence of infections such as tuberculosis. The recognition of anemia during pregnancy with adequate treatment is unquestionably a factor in the decrease of maternal mortality. Too much stress cannot be laid upon this element of antenatal care. Even though we have today, in our armamentarium, many methods of combating anemia, it is probably one of the most frequently overlooked complications of pregnancy and parturition, and if the presence of the disease is unrecognized, these valuable adjuncts of medical treatment are of no avail. If anemia is discovered, adequate treatment should be instituted at once, and the patient should be observed most carefully during the entire pregnancy, in order to keep the blood count at a proper level.

## CLINIC OF DR. BURGESS GORDON

JEFFERSON HOSPITAL

---

### THE INDICATIONS FOR AND THE TECHNIC OF ARTIFICIAL PNEUMOTHORAX

THE idea of employing artificial pneumothorax for the treatment of pulmonary tuberculosis was conceived with the sound principle that immobilization is valuable for the control of inflammation in any part of the body. The history of its use, according to Myers,<sup>1</sup> dates back to the fourth century when Greek physicians introduced air into the chest for the treatment of disease. James Carson, a Scotch physician practicing in Liverpool, was apparently the first to conduct experiments on animals and he collapsed a lung successfully in 1888 by introducing air into the pleural cavity. His experimental studies were significant because Itard, Selle, and others had observed that patients could breathe satisfactorily and survive with spontaneous pneumothorax. Although Carson recommended artificial pneumothorax for the treatment of pulmonary tuberculosis he did not use it on patients and thus his writings received little attention clinically. Carl Forlanini of Italy recognized the possibilities of collapse therapy and in 1888 performed the first artificial pneumothorax on a patient with pleural effusion and four years later he actually collapsed a diseased lung. Murphy of Chicago used the method successfully in 1898 and is credited, with Forlanini, as having established the clinical value of pneumothorax. Samuel Robinson of Boston, according to Stoll,<sup>2</sup> was the first to employ pneumothorax treatments in the eastern part of the United States and devised an apparatus for the purpose; his first case was a patient of Dr. Joseph Pratt. Brauer, McRuer, Tice and Lumke are other names connected with the early work of artificial pneumothorax.

From the earliest times the suggestion of new methods of treatment has been followed almost always by waves of criticism, skepticism and enthusiasm. Artificial pneumothorax, no exception, has been alternately condemned and supported, even by the most celebrated workers in tuberculosis. The reason for this is traceable, no doubt, either to the observer's good fortune or misfortune to witness a group of striking recoveries or a series of catastrophes; impression rather than experience has also played a part. As a result, there has been a tremendous volume of contradictory literature. It is evident in some publications that the unfavorable results were due to the improper selection of cases, and conversely that the favorable results in other cases would have occurred in the ordinary course of healing. Thus, one gains from the literature that collapse therapy in tuberculosis requires a certain knowledge of the physiopathology of the disease.

#### PHYSIOLOGIC CONSIDERATIONS

Since rest is an important measure in the treatment of pulmonary tuberculosis there is a tendency to ascribe the beneficial results of artificial pneumothorax to the degree of immobility of the affected lung. However, experience indicates that the degree of collapse is not necessarily an indication of the degree of healing that may occur. It has been noted, for example, that a moderately collapsed and functioning lung sometimes shows greater improvement than an extremely collapsed and nonfunctioning lung. The results are no doubt influenced by the type of infection and the individual's natural resistance, and also related to the degree of contractility and expansibility of the lung, the drainage of suppurative areas, inflammatory processes located near the base of tugging adhesions, cavity formation, shifting of the mediastinum, and the traumatizing effect of cough.

Under normal conditions the lungs completely fill the pleural spaces and thus the pleural surfaces are actually only potential cavities. The pleural spaces contain serous fluid, a strong adhesive force which causes the lungs to be retained against the chest wall. Since the lungs contain a considerable amount of elastic tissue they exert a constant pull away from the chest wall. Due to the adhesive effect of the serum upon

the pleural surfaces and the normal contractility of the lung, a negative intrapleural pressure is created. The pressure is approximately 9 mm. of mercury at the end of inspiration and about 7.5 mm. at the end of expiration; there is a considerable variation in different individuals. Thus, it becomes evident that there is a difference physiologically between collapse and compression of the lung in artificial pneumothorax. Collapse is actually a relaxation of the lung due to a comparatively small amount of air having been introduced into the pleural space; the separation of the pleural surfaces definitely interferes with the adhesive action of the serous fluid and permits the lung to contract. Compression signifies that a definite force has been exerted upon the lung by a relatively large amount of air introduced into the pleural cavity. This causes a marked reduction in the negative pressure, a tendency to develop a positive pressure. Thus, the lung is no longer able to expand freely; eventually it becomes compressed.

The significance of the various changes in intrapleural pressure is illustrated further in studying the effects on the mediastinum. In normal individuals the mediastinum is so mobile as to be easily shifted from its medial position to one side or the other. With small changes in the pleural pressure on one side of the thoracic cavity there is little or no influence upon the mediastinum or on the opposite lung. However, the introduction of a large quantity of air under high pressure into one pleural cavity will not only compress the lung on this treated side but will also influence the lung on the opposite side due to displacement of the mediastinum. This results in lowered vital capacity, causing dyspnea; and in some cases there are signs of a disturbed pulmonary circulation. With a fixed mediastinum the problem is different and larger quantities of air may be introduced without influencing the opposite lung. However, the desirability of this measure upon the diseased lung is open to question, since tuberculous tissue, as with other inflamed tissue, is easily damaged by pressure and distortion. This is illustrated in the progression of processes at the base of adhesions, the changes being related to the "tugging" movements during expiration. Thus, while the high intrapleural pressure compresses the lung generally the adhesion causes it to remain expanded at one point. It appears further

that cough is more apt to disturb the compressed and more or less immobilized lung than the contracted or relaxed lung, possibly due to differences in buoyancy. In regarding the problem physiologically it seems that the ideal amount of air for introduction into the pleural cavity is that which is sufficient only to cause relaxation, resulting in a moderate collapse of the affected lung.

So-called "bilateral pneumothorax" is physiologically sound in selected cases providing a negative pressure is preserved at least on one side. The reason for this provision is explained by Graham<sup>3</sup> who points out that the passage of air down the trachea and into the lungs is essentially a suction process and is therefore dependent upon the existence of a negative intrapleural pressure at some time during the action of inspiration.

#### SELECTIVE PNEUMOTHORAX

A physiologic phenomenon which is closely related to the pathology of pulmonary tuberculosis is so-called "selective pneumothorax." It appears, according to Myers,<sup>1</sup> that diseased areas, with the exception of consolidations and dense fibrosis, collapse more readily than normal areas owing to the fact that in such areas there is little or no diminution of contractility but rather a marked impairment of expansibility. This favors the mechanism of selective collapse which is essentially a collapse of the diseased part of the treated lung and a more or less normal function of the unaffected part. According to Cutler,<sup>4</sup> the mechanics of selective collapse are attributed to the inability of tuberculous tissue to resist the pressure of the pneumothorax and, thus, with each inspiration the expansion of the part becomes less and less. Conversely, the normal part of the treated lung which has retained its normal elasticity will resist the pressure of the pneumothorax. Due to the expansile action of the normal part air in the pleural cavity will be forced toward the diseased area. Thus, the diseased area gradually yields and becomes collapsed. Ehrenberg,<sup>5</sup> differing with this general view, regards Archimedes' *Principle of Buoyancy* as the cause of selective collapse. This implies that the air within the lung is of higher density than the air within the pleural cavity, and thus a buoyant force will be transmitted through the alveoli by the air in the air passages upon the gas

in the pleural cavity. As a consequence, the air in the pleural cavity will be forced upward and its bulk will accumulate over the apex of the lung. Thus, the upper lobe, due to gravity and the pressure of the insufflated air, will not only be separated from the chest wall but may even drop to the first or second interspace. According to Ehrenberg the satisfactory results of such a collapse are due to the fortunate location of the lesion at the point where the gas accumulates.

#### PATHOLOGIC CONSIDERATIONS

Numerous observations indicate that no serious harm occurs in the normal lung which is maintained in a collapsed state over a long period of time. The chief alterations are the development of fibrous tissue in the pleura and variations in the blood vessels. The degree of permanent change appears to be somewhat dependent upon the underlying pathology.

According to Charr<sup>6</sup> there is a decrease in the number and caliber of the pulmonary blood vessels. The finer ramifications begin to disappear while the larger vessels become short and narrow, within about two months after collapse is instituted; there is marked thickening of the adventitia with proliferative endarteritis. The changes tend to become permanent if the collapse is maintained for one year or more.

The bronchi and bronchioles show atrophy and sclerosis. Infiltrating into the collapsed lung are fibrous strands which originate in the adventitia of the blood vessels, the connective tissue of the interlobular septa and the pleura. Pleural exudate augments fibrous tissue formation, which later invades the parenchyma whether it is normal or diseased. Graham<sup>7</sup> suggests that pneumothorax incites proliferation of fibrous tissue at least in the pleura. In the lung that has been allowed to reexpand there are fibrous adhesions between it and the chest wall and not infrequently there is obliteration of the pleural space.

There are differences in the closure of cavities. Charr<sup>6</sup> rarely found a complete flattening or proximation of cavity walls, even in those cases where collapse had been satisfactory and the disease stabilized. Three cases that had been followed by the x-rays showed a gradual enlargement of the cavity in the atelectatic lung; postmortem suggested this was due to

the retention of necrotic matter. A few were obliterated or transformed into scar tissue, the result apparently of relaxation of the tissue surrounding the cavity wall. Evidently the closure and healing of cavities depend upon satisfactory drainage, the absence of check valves which would favor the retention of air and dilatation of the cavity, as well as upon any relaxing or forceful action of artificial pneumothorax.

#### INDICATIONS FOR ARTIFICIAL PNEUMOTHORAX

In considering the indications it is important to realize that tuberculosis is a variable and treacherous disease. It is characterized by periods of exacerbation and improvement that are sometimes difficult to explain on the basis of the extent and degree of infection. Patients may improve without apparent cause or there may be a retrogression even when the most careful methods are employed. In some instances experienced workers in tuberculosis cannot predict the outcome. Thus, a good deal of judgment is required in the selection of cases for collapse therapy as well as in their successful conduct over a long period of time. The well-established hygienic-dietetic-rest regimen should be tried in almost all cases before instituting pneumothorax. Enthusiasm for artificial pneumothorax should be carefully checked in cases that are progressing satisfactorily. The procedure is not entirely without danger of complications, and furthermore it must be continued indefinitely. Since it is essentially a supplementary measure to the general regimen there should be no false encouragement as to its replacing any fundamental treatment.

The indications for unilateral artificial pneumothorax are as follows:

1. The most obvious need for collapse therapy is in those patients with active progressive disease of one lung which is not responding to a carefully regulated hygienic-dietetic-rest regimen. In such cases there is danger that the infection will spread to the opposite lung and to the unaffected part of the diseased lung.

2. In patients with a lesion that has become stationary. The need for collapse is less urgent but the instability of the temperature and pulse rate with other evidences of toxemia emphasize the potential danger of the disease.

3. In complications, such as diabetes, tuberculous laryngitis, and recurring or severe hemoptysis, the latter being limited to cases in which the site of bleeding is quite definitely established.

4. In cases of advanced or bilateral disease with approximately one third of normal pulmonary tissues remaining, but without evidence of emphysema; the general condition should be reasonably good in spite of any toxemia.

5. To control the persistent formation of fluid in pleurisy with effusion.

6. To maintain a collapse of the lung in spontaneous pneumothorax which is due to tuberculosis.

7. In all unilateral cases first diagnosed during or immediately following pregnancy.

8. In patients with "open" tuberculosis who are uncooperative at home and cannot be treated in sanatoria.

The indications for simultaneous bilateral artificial pneumothorax are:

1. In cases with reactivation or extension of the infection in the relatively good lung, and in processes that are essentially equal in both lungs; the cases should be of the ulcerative type with cavitation.

2. To control toxemia after the original pneumothorax has been established.

3. In cases with displacement of the mediastinum and in recurring hemoptysis of the hitherto untreated lung.

An important point in the selection of cases for unilateral artificial pneumothorax is the consideration of contralateral disease, *i. e.*, the possibility of stirring up trouble in the relatively sound lung, either because of extra work thrown upon it or because of displacement phenomena of the mediastinum. Sometimes the exact effect can be determined only by a therapeutic test. As Matson, Matson and Bisailon<sup>8</sup> have pointed out the various types of contralateral lung processes vary greatly in their prognostic significance. In general the lung to be treated should be considered as to its degree of activity rather than the extent of involvement; the lesion in the opposite lung should be regarded as possibly related to the more active and extensive process in the lung to be treated. The importance of considering the degree of activity as more important than the extent of the lesion, *per se*, is emphasized in the

marked reduction of toxemia and pulmonary symptoms that sometimes occurs in patients who would be given up as hopeless if judged entirely on an anatomic basis. A bilateral case may be selected for collapse of one lung if this markedly diseased lung presents evidence of chronic change and the opposite lung shows comparatively less disease or a slowly progressive infection. This dictum should at least be considered correct until proved otherwise.

The use of simultaneous bilateral pneumothorax in advanced cases with cavitation has an increasing number of advocates and the results have justified the treatment. Strict bed rest is essential in almost all instances.

Phrenic paralysis in combination with artificial pneumothorax may be employed in bilateral cases with advanced fibrotic lesions on one side and earlier and rapidly advancing lesions on the other; the pneumothorax is used to collapse the less affected lung, the paralysis being utilized on the opposite side.

In the selection of cases according to sex there is no need to differentiate; the sexes react essentially the same. There is an increasing tendency to treat children with the adult type of tuberculosis according to the indications for adults. Gross and English<sup>9</sup> find that juvenile patients who harbor the adult form of tuberculosis do poorly under the usual hygienic-dietetic-rest regimen. They strongly advocate the use of artificial pneumothorax. It should be emphasized that collapse therapy is not indicated in the childhood type of tuberculosis. It may be used in patients up to sixty years of age.

### CONTRAINDICATIONS

The contraindications are: cardiac failure, emphysema, asthma, renal disease, and gastro-intestinal tuberculosis. The danger of inducing artificial pneumothorax in emphysema cases should be stressed. Such patients are greatly disturbed; the procedure may prove fatal. It is important to emphasize also that the degree of emphysema may be underestimated, also that the underlying tuberculous infection may be masked. A flattened diaphragm with increased illumination of the lung fields in the x-rays are warning signs of emphysema.

## DESCRIPTION OF PNEUMOTHORAX APPARATUS

Practically all pneumothorax apparatus may be classified according to the principle involved as follows: the gravity principle, gasometer principle and aneroid-recording principle.

In the gravity type, of which the Samuel Robinson apparatus is an example, there are two bottles, one of which introduces air into the pleural space as the water from one bottle passes into the other, according to the physics of displacement.

The gasometer type, of which the Bethune apparatus is an example, consists of two cylinders constructed as a telescopic couple; the air passes through a connecting tube as the inner cylinder descends.

The aneroid-recording type<sup>10</sup> consists of an aneroid chamber, the movements of which, in response to the changes in intrapleural pressure are recorded on a chart moved by means of a kymograph.

Apparatus consisting of one or more syringes should not be used if their principle depends upon forceful pressure.

Filtered atmospheric air is now commonly used in all introductions. The pneumothorax needle should be a No. 19, 3½ inches in length, a small curved bevel, with a convenient nipple for connecting with a syringe or rubber tubing. There are special needles providing cut-off valves with or without side openings at the tips, as for example, Loving's needle, the Saugman and the Floyd needles.

## THE TECHNIC FOR INTRODUCING THE THORACENTESIS NEEDLE

The technic for introducing the needle requires experience, judgment and care; certain steps should be routine. Before introducing the needle the patient should be fluoroscoped in the upright position, then placed on an operating table with his affected side elevated and supported by a pillow. The fifth or seventh interspace in the midaxillary line or slightly posteriorly is selected and the site painted with a tincture of iodine and washed with alcohol. A small sterile sheet with an opening about 4 inches in width and 8 inches long is placed over the chest in such a manner as to expose the site of operation. An injection of 0.5 per cent novocain is made under the skin until a wheal is produced: then a small incision about 1 mm. in length is made with a pointed scalpel and a number 22 needle

Fig. 64—The technic of anesthesia and the introduction of the needle in an initial artificial pneumothorax. (Collected papers dedicated to Henry A. Christian; B. Gordon.)

FIG. 15.—The collapse of the lung, and the corresponding intrapleural pressures in progressive artificial pneumothorax, as traced with the recording apparatus. (Collected papers dedicated to Henry A. Christian; B. Gordon.)

is introduced to carry the anesthesia into the deep tissues of the chest as far as the pleura (Fig. 64, *A*). These procedures, except for the initial hypodermic injection of the skin, should be entirely free from pain. After the local anesthesia has been obtained the pneumothorax needle attached to a syringe containing salt solution is slowly and carefully introduced at an angle of about 85 degrees (Fig. 64, *B*). At intervals the plunger of the syringe is carefully withdrawn in order to obtain any evidence that the needle has entered a blood vessel (Fig. 64, *B*). As the needle reaches the parietal pleura there will be a sense of resistance which is lost as it passes into the pleural space; in some instances the point will be felt "scratching" against the lung (Fig. 64, *C*). The syringe is then detached to allow air to enter the pleural space which may occur as a result of the negative pressure; then the syringe is reattached and the plunger "pulled." If bubbles rise in the column of fluid it is certain the needle is in the pleural space (Fig. 64, *C*). The needle is then ready for connection with the pneumothorax apparatus (Fig. 65).

#### THE USE OF THE APPARATUS

**The Initial Pneumothorax.**—In using Samuel Robinson's apparatus (Fig. 66), bottle "B" is elevated, valve "P" turned parallel (open) with the wood back, and valve "M" moved to the vertical position (closed); valves "K" and "L" are then opened (horizontal and vertical positions respectively) in order to bring the manometer and the pleural cavity into communication; with these positions the bottle system is completely shut off.

With the pneumothorax needle in the pleural cavity and connected with nipple "H" of the apparatus the water column will rise in the manometer and show oscillations of negative pressure. This indicates a free pleural space and air may be introduced with safety. Under no circumstances should air be given if there are slight negative and positive oscillations or no greatly sustained negative pressure as such readings suggest that the needle is in the pulmonary tissue. To introduce air, valve "K" is moved to the vertical position (closed) and valve "M" turned to the horizontal plane (opened). This shuts off the manometer and brings the pleural cavity into communica-

tion with the air in bottle "A." The water column in bottle "B" will gradually descend as it enters bottle "A," thus displacing air from bottle "A" into the pleural cavity. The rate of flow is governed by the height of bottle "B." Valve "K" may be kept open during the entire treatment so as to obtain oscillations in the manometer.

After introducing 25 cc. of air, valve "M" should be closed and valve "K" opened. This stops the flow of air and the manometer will record the intrapleural pressure. After noting the oscillations and if the intrapleural pressure is still negative a further small introduction of air should be given as previously. These steps are repeated until the patient has received

Fig. 66.—Samuel Robinson's artificial pneumothorax apparatus.

between 100 and 200 cc. of air. The treatment should be stopped at any time if the patient complains of pain or shortness of breath, regardless of the pressure and how much air has been introduced. In cases showing tension pneumothorax due to an excessive introduction, some of the air should be removed with a special syringe;<sup>11</sup> it is inadvisable to use the pneumothorax apparatus for this purpose.

Following the initial pneumothorax treatment it is important to examine the patient fluoroscopically and preferably in the same position as was used for the introduction of air. With the horizontal examination the pneumothorax cavity will be clearly visualized, then if the patient is placed in the upright position, the air will shift to a localized position in the

upper part of the chest. Thus, it is possible to exclude the presence of adhesions; if adhesions are present, the air will remain in the original pneumothorax pocket. This study is also valuable for determining any possible displacement of the heart and mediastinum.

**Refills.**—After the pleural surfaces are definitely separated, all subsequent introductions of air are known as “refills.” If Samuel Robinson’s apparatus is to be used it is set up as previously and the readings are taken after each introduction of 50 or 100 cc. After bottle “B” has been emptied, bottle “A” should be raised and bottle “B” lowered so that the water will be siphoned into bottle “B”; the passage may be started by connecting bulb “F” to nipple “H” and giving one or two compressions; then bottle “B” is raised and bottle “A” lowered, which makes the apparatus ready for use. The treatment is stopped when the pressure becomes approximately minus 2 or neutral or up to plus 2; experience shows that comparatively few patients do well if high pressures are used. If the pneumothorax pressure is excessive, some of the air should be removed; a special syringe<sup>11</sup> or a decompressor<sup>12</sup> may be convenient.

A selective pneumothorax will be obtained most frequently if small introductions are given every three or four days at first, then increasing the intervals to one week, and gradually to ten days or longer. All patients should be fluoroscoped before treatment. In bilateral pneumothorax cases the air may be introduced into each pleural cavity on the same day or alternated. If a positive pressure is used on one side, the other should be definitely negative. Every attempt should be made to maintain a normal position of the mediastinum.

#### DANGER SIGNALS IN ARTIFICIAL PNEUMOTHORAX THERAPY

MacKay<sup>13</sup> has described the immediate dangers to the patient during the administration of artificial pneumothorax, stating that while the accidents are probably unavoidable they are frequently serious and sometimes fatal. Of these the most serious is air embolism, due to the introduction of air into a pulmonary vein. It is suggested by a lapse of consciousness, signs of shock and of cerebral involvement. Sudden severe pain in the chest with dyspnea is a strong indication of spon-

taneous pneumothorax, the result of an injury to the lung. Pleural shock is apparently less common; it may be related to a vagovagal reflex. Cocke<sup>14</sup> believes that a progressive fall in blood pressure and pulse rate, with gradual loss of consciousness, flaccidity, a disturbance of reflexes, sweating, slight clonic movements of the face, upper limbs and trunk, are suggestive. Pleural effusions may occur as delayed reactions and are often attributed to high intrapleural pressures. The complications of bilateral pneumothorax are essentially the same as in the unilateral type except that spontaneous pneumothorax is apt to be more common; laughing and loud talking place undue strain on the lungs and are factors in some instances.

#### THE MANAGEMENT OF ARTIFICIAL PNEUMOTHORAX CASES

Regardless of the striking results in artificial pneumothorax cases the usual hygienic-dietetic-rest regimen should be continued. Appearances and symptoms may be confusing, especially when the physical signs are absent as in a well-collapsed lung. It is perhaps a safe rule that the patient without toxic manifestations may sit in a chair two months after a satisfactory collapse has been obtained and begin to walk slowly for short periods six months later. The blood sedimentation test is considered to be an index of the activity of the lesion and should be used in all doubtful cases. The intervals between treatments and the amount of air to be introduced depend upon the degree and type of collapse, and the general effects. It is an ideal plan to strive for a selective collapse.

In patients who fail to improve with collapse therapy two causes should be considered: (1) Is the affected lung being properly collapsed? (2) Is there a spread to the opposite lung? With an unsuitable collapse pneumolysis may be advisable. This operation requires special training and cases should be referred to a competent surgeon. Some cases will eventually require thoracoplasty. Processes that develop in the opposite lung, despite a satisfactory collapse of the originally treated lung, should be considered for phrenic paralysis or artificial pneumothorax. Oleothorax may be of value in preventing expansion of the lung due to the development of adhesions.

In basal pulmonary tuberculosis with an unsatisfactory col-

lapse of the affected area the use of abdominal compression<sup>15</sup> or phrenic paralysis as a supplementary measure may be valuable.<sup>16</sup>

#### INDICATIONS FOR TERMINATING ARTIFICIAL PNEUMOTHORAX

Artificial pneumothorax should be discontinued because: (1) of a complication on the affected side, as for example, recurring spontaneous pneumothorax or pleural effusion; (2) a spread of the disease to the opposite lung in which collapse measures are inadvisable; and (3) uncontrolled infection of the affected lung. Some cases terminate themselves due to the formation of adhesions in spite of the most exacting artificial pneumothorax treatments.

The voluntary reexpansion of the lung should be considered as follows: (1) minimal cases treated successfully for two years; (2) moderately advanced cases without marked cavitation after four years' treatment; (3) far-advanced cases with cavity formation, after five to seven years. All reexpanding cases should be followed closely with physical examinations and the x-rays. If there is any question of activation the pneumothorax should be reinstituted. It is usually advisable in long-treated cases to consider thoracoplasty, rather than to resort to further pneumothorax.

In evaluating the results of artificial pneumothorax it becomes evident that the proper selection of cases, knowledge of the mechanics of respiration, and a carefully regulated medical regimen play an important part in the results. Artificial pneumothorax is not a procedure for haphazard use; it has limitations and is not without danger. It should not be considered in any sense as a substitute for general measures; there is far more involved than simply the introduction of air into the pleural cavity.

## CLINIC OF DR. N. W. WINKELMAN

GRADUATE SCHOOL OF MEDICINE,  
UNIVERSITY OF PENNSYLVANIA

---

### DIAGNOSIS AND TREATMENT OF HYSTERICAL APHONIA AND THE DIAGNOSIS OF MALINGERING IN THESE CASES

HYSTERICAL aponia is one of the most common forms of psychogenic paralysis. In order to understand the term it is first necessary to define these words. By hysteria is meant a condition characterized by changes in mood or affect, with alterations in character or personality and with physical or somatic manifestations. Every case of hysteria usually has all of the above characteristics, although one of them predominates and gives the characteristic coloring to the clinical picture. In aponia of hysterical nature, it is the difficulty in talking which overshadows the clinical picture, although the other manifestations are also present to a lesser degree. The term "aphonia" signifies an "absence of voice." This term is not entirely correct in the designation used because, as a matter of fact, there is usually a hoarseness or whispering type of speech rather than a complete absence of all vocal manifestations. When even the whispered voice is absent the term "absitheria," which has been coined by Dr. Chevalier Jackson, is applied.

To understand the mechanism of the problem we must give a brief résumé of the present-day conception of hysteria. Hysteria is regarded as a "flight into disease." It is usually an ineffectual but a determined effort on the part of the patient to escape from reality. It represents the best solution for adjustment that he can make. Usually the effort is poorly carried out and the plan is frequently infantile, and is often an impossible one, but it is a purposive effort notwithstanding.

The physical manifestations are the result of repression in the unconscious of unpleasant experiences which are prevented from reaching consciousness because of their painful associations. Every hysterical symptom has a definite meaning and no therapy can be successful without recognizing this basic fact. It is true that the symptoms may defy direct interpretation but usually the significance and the psychogenic origin can be detected by "probing" beneath the surface. It may require hours of work with the patient before the interpretation of the condition is correctly made.

If the above tenets are correct, then an aphonia of hysterical origin must have as its basis an unconscious or uncontrollable desire on the part of the patient to prevent audible speech. The reason for this is not identical in every case, as will be illustrated.

#### REPORT OF CASES

**Case I.**—An insight into the mechanism of hysterical aphonia is afforded by a woman of forty-five, who was studied many years ago at one of the local hospitals. Her chief complaint was an inability to speak above a whisper. She was a clinic patient and was emaciated and showed the terrific strain of life. On account of her ignorance it was impossible to analyze her by the usual methods and no cause for the loss of voice could be uncovered. Various methods of treatment then in vogue were tried but without success. It was finally determined to try the effect of light etherization. It was argued that possibly during the excited stage of anesthesia the patient would cry out and if the crying could be continued until consciousness returned the speech mechanism might be restored to normal. The patient was willing to cooperate and light anesthesia was induced. As predicted the patient began to mumble during the excitement stage and finally cried out rather suddenly in an extremely loud tone, "God damn you, John, I won't call you." The anesthesia was immediately stopped. The patient was crying and talking at the time that she regained consciousness and her speech was restored to normal.

With the patient's statement as a clue and with the patient's cooperation, it was rather easy to reconstruct her story. Her husband was a drunkard and many times came home late

and intoxicated. In the morning it was necessary to call him many times before he was able to arouse himself sufficiently to go to his work. It was her practice to have the entire breakfast prepared prior to calling him. It was not unusual for the husband to quarrel with his wife and occasionally strike her for no apparent reason. She suffered many body and facial bruises as the result of his temper in the morning. She told us that on one occasion her nose was broken. She eventually became extremely fearful about awakening him because it would mean verbal abuse at least and sometimes physical violence. In view of the fact that her children came down to breakfast at the same time it was impossible for her to run to the second floor to call him but it was necessary to yell to him on several occasions before he would be awakened. With the onset of the aphonia, of course, she was unable to call her husband. She noted that since her loss of voice her husband had been more solicitous.

In an analysis of a case of this sort the underlying mechanism is very clearly brought out. The patient's hatred toward her husband as the result of his abuse can be very easily suspected from even a superficial study. Her desire not to awaken him in the morning was a very natural one. She, therefore, assumed the only defensive mechanism that she could to prevent arousing him in the morning. This served a double purpose. It incited a little sympathy in him and was a defense against calling him in the morning. It was, however, not a rational procedure because their livelihood was endangered.

A case of this sort is frequently easily cured of the presenting symptom of aphonia but the underlying family situation is not relieved thereby.

**Case II.**—A priest, aged fifty-five, was referred by Dr. Chevalier Jackson. His chief complaint was inability to speak above a whisper. He had been in charge of a large church in an adjacent city for many years. His work had been interesting and he had developed an implicit faith in his religion and his parish. He acted as counselor and as a friend to his people. He would help them with their business ventures and he had always found them honest. Just before the financial

depression he was asked to sign notes for two members of his congregation. He had done this on so many previous occasions that he did not hesitate. The depression came and both of the men for whom he had signed the notes lost heavily in their business ventures. Both disappeared from the city within a period of two weeks without leaving their forwarding addresses. It was, therefore, necessary for the priest to make good on both notes. When he came to see us he was paying small amounts to the bank every month for these notes. As the result of these dealings with people who had professed faith in religion, he had lost his belief in human beings and in religion in general. He, therefore, found his enthusiasm gradually waning and became more and more discouraged in his dealings with human beings. Suddenly an aphonia developed which was a means of escape from duties that were gradually becoming odious to him.

His aphonia was easily relieved by strong suggestion, re-enforced by faradic stimulation, but his faith in religion was still shattered. It has been several years since he has fully recovered his speech, but he tells me that he is unable to put into his work the enthusiasm that he did prior to the development of the aphonia.

**Case III.**—A school teacher of thirty was referred by Dr. Chevalier Jackson because of difficulty in speaking. In a detailed survey of her life these factors stood out. She lived in a small town; and her parents were at odds with each other. She did not live at home because of the family difficulties. Her family insisted on her telephoning them every day. She was ashamed of what was going on because of the scandal that was caused by her parents' marital difficulties. She also felt that it was spoiling her matrimonial chances. She was also a Sunday school teacher and she felt somewhat abashed to talk on religion and conduct to her Sunday school class in view of everyone's knowledge of her own family difficulties. She was ashamed to go out into public places. The conditions preyed on her mind to such an extent that she became seclusive. With the onset of the aphonia, however, her one problem was solved, although her other problem of earning a livelihood was jeopardized.

Assured by Dr. Jackson and his staff that there was no organic difficulty associated with her loss of voice, it was very easy to effect an almost immediate relief of the aphonia by strong suggestion. Frank discussion of her problem had the effect of giving her a different outlook on the entire situation. She left Philadelphia completely relieved of the hysterical symptom and with an indifference to her family problems because of her realization that she herself was not to blame for the dissensions between her parents.

**Case IV.**—Mr. W. was referred by Dr. Chevalier Jackson because of aphonia. The patient was a minister. He also did a great deal of singing and talking. He had been engaged in this type of work for about twenty-three years and had had no difficulty until approximately two years before we saw him. He noted gradually that it required more and more effort for him to speak. He was compelled to give up his work in February of 1935 because he found that he was unable to speak above a whisper. He consulted many throat specialists and was told by some that he had laryngitis. No improvement resulted from a great deal of treatment, including local applications, and osteopathic and chiropractic adjustments. He found that when he was singing as a guest in another city his speech was improved but in his own church his difficulties became markedly intensified. With this clue the family situation was gone into very carefully. He confessed that there was considerable difficulty with his wife. She was sexually frigid. About ten years before the onset of his difficulty, his wife engaged a boy of sixteen to help with the housework. He was not suspicious of the boy until a few years later when he came upon him and his wife suddenly and found them embracing and kissing. His wife's excuse was that her feeling for the boy was that of a mother. It was only after considerable wrangling that his wife permitted the boy to be discharged. She kept in communication with him for a period of about three years. The patient's mother-in-law, who was living with them, had frequently warned him about her daughter's infidelity. After the boy left the house he proceeded to discard the entire matter from his mind, but later his suspicions became directed against a man who was having dif-

difficulties with his own wife. On several occasions the patient found his wife in rather compromising situations with this man, for whom she admitted a great deal of sympathy in view of his marital difficulties. She planned and made trips to New York with him and many gifts came to the house from this man. There was no doubt in his mind that his wife was maintaining a clandestine affair.

During the time while he was away from his home his mother-in-law would occasionally write him letters airing her suspicions to him about her daughter. This would have the effect of disturbing him to such a point that it interfered with his work. Gradually his speech difficulty became so great that he was unable to carry on his work and remained at home doing odd jobs not connected with church affairs.

It was not difficult to relieve this patient of the presenting symptom of aphonia, but it was extremely difficult to acclimate him to what was going on at home. There was financial difficulty because of his inability to work and, in addition, his children were suffering because of the tense family situation. The patient has since left Philadelphia and has gone to a distant city to do another type of work not associated with the church, which does not demand vocal exertion. His wife is not with him.

A differentiation from malingering or feigning is necessary in every case of hysterical aphonia. To state glibly that hysterical aphonia is the result of an unconscious repression and malingering a conscious one does not help in their clinical differentiation. It is true that most persons tend to exaggerate their complaints and particularly so when the question of compensation comes into play. This, however, is not malingering in the psychiatric sense. The true malingerer consciously tries to simulate signs and symptoms for the purpose of monetary gain or to evade responsibility. The fundamental psychologic distinction is that the malingerer consciously attempts to deceive while in the hysteric the manifestations are unconsciously determined and beyond his control. Mutism is a much more common form of malingering than is aphonia. A careful survey of the entire clinical picture will usually suffice to make a distinction, although at times even the most expert may be baffled.

As a general rule the malingerer is not anxious for medical examination because he fears detection. The hysteric, on the contrary, usually welcomes medical study. Frequently the malingerer can be caught off guard when he believes he is not being watched. It is not infrequent for the person to talk when he is not aware that he is being observed medically. A hysteric cannot be caught "off guard" in this way.

A great many psychologic "tricks" have been devised to "catch" the malingerer. During the World War it was not uncommon to find malingering in the drafted men. Psychologic tricks were devised to confuse the person during the test such as dropping a coin in back of the person who claimed deafness; two-colored glasses when blindness in one eye was claimed, and so on.

A thorough knowledge of the neurologic and psychiatric manifestations and thorough study of the patient will serve as the best differentiating medium between hysteria and malingering.

In the treatment of hysterical aphonia a sharp distinction must be made between the treatment of the presenting symptom, the aphonia, and the treatment of the underlying condition, the hysterical personality.

In the treatment of the aphonia the therapist must have a combination of tact, art, self-assurance and, last and not least, knowledge. Yet with all of this the inaccessibility of the patient himself may prevent a good result. There is no doubt that the personality of the therapist plays a tremendous rôle in the treatment. That actual knowledge is not a requisite can be judged from the excellent results obtained by quacks in the treatment of conditions of this type.

The tact of the therapist is shown by his handling of the patient. The patient will resent any suggestion by doctor or relative that his condition is "imaginary." It often provokes greater resentment and renders the problem much more difficult, if not impossible. A complete study of the patient must be made in order to convince him that his problem has been taken seriously. This will include a detailed history, consisting of a social and psychiatric study and a very careful physical examination. It must be explained to the patient that the fact that nothing of an organic nature is found to account for the

symptoms does not mean that he is not ill. It must also be carefully explained to the patient that a nervous disease is like any other illness and it requires treatment for its relief. It is wise, at times, when the patient is intelligent, to give him an insight into the mechanism of hysteria and explain the rôle played by the various emotional factors. This will dispel for the patient the fear that his condition is entirely the result of his imagination. An error is often made to concentrate the patient's attention on somatic conditions. To claim that an aphonia is the result of "laryngitis" is to give the patient a self-satisfying explanation for his complaints. No local instrumentation or operation should be suggested because they only tend to perpetuate symptoms which should be easily removed by psychotherapeutic measures.

The method and means of therapy will vary with the individual therapist. Any therapeutic measure which promises relief is indicated and justified. There is no objection to the use of medicaments, electricity or hypodermic injections, provided the physician realizes that he is using these as suggestive measures to influence the patient psychically. No two patients can be treated alike. The therapist must realize, however, that he cannot expect the medication or other suggestive measure to clear up a severe mental conflict or to adjust some family situation.

Suggestion plays the major rôle in the treatment, but the susceptibility of these patients to suggestion has been over-emphasized. It is true that a symptomatic cure of hysterical aphonia can easily be accomplished with suggestion alone, but we should go beyond this. For immediate relief of the presenting symptom, strong suggestion or even hypnosis may be employed, but the goal is to find the forces which have caused the repression. One should not be satisfied with the clearing up of the hysterical manifestation but should probe into the mechanism of the condition, without subjecting the patient to a prolonged psychoanalytic procedure. It is necessary in most cases to complete the study and give the patient an insight into the mechanism of the problem as quickly as possible. The personality defect must also be subjected to minute investigation and must be corrected if at all possible. It is to be stressed that most of the patients can be treated in one's

office without interruption of their routine of work. This is also a very important point because not only must the patients' time be occupied, but also they are earning enough to take care of their obligations. They also have impressed on them the fact that they are not sick enough to stop their work.

It must be recognized that the patient had made a "flight into disease" as a means of solving what to him had become an intolerable situation. All the facts of his difficulties must be obtained so that the therapist will know the conditions from which the patient is making an escape. A frank discussion of his problem is essential. It must be realized that the therapist is unable to adjust family difficulties or financial reverses, but he can reeducate the patient to reconsider his problems and to readjust himself to conditions. It is manifestly impossible for the therapist to correct an erring wife, as in Case IV, or to cure the alcoholic cravings of the husband of our first patient. Sufficient time should be taken with the patient to go over the entire situation, to make the patient more satisfied with his lot, to try to get him to seek other outlets for his energies, and to take an interest in outside affairs. A good many of our patients have been school teachers who have reached the age where marriage is a forlorn hope. To hold out hope to patients of this sort for matrimony is wrong, but to educate them to be satisfied with their lots is essential.

As a rule a prolonged psychoanalysis is not indicated in these cases. While intensive analysis revealing the basic psychogenic factors may be desirable in certain cases of hysteria, it is unnecessary and frequently undesirable in the great majority of these hysterical individuals who show but one symptom of that disease. At no time should the patient be accused of not desiring to get well because it indicates a poor understanding on the part of the doctor. Even when this is suspected it should be made part of the psychotherapeutic procedure and not the topic for argument or accusation.

As the patient's entire life is reviewed before us, we can frequently give the patient a little insight into his own problem by appropriate hints during the recital. This is frequently part of the therapeutic procedure and is of value in helping the patient to solve his problem.

My own procedure in a case of hysterical aphonia is to obtain a detailed history from the patient at the first consultation. A great many significant facts can be uncovered in the first interview, but at times repeated interviews are necessary before the complete story can be obtained. The entire sequence of events leading to the loss of voice can frequently be disclosed in the course of five or six interviews. During this time treatment for the somatic symptom is undertaken after a thorough physical study. As a rule these cases have been referred by laryngologists who have completely ruled out any organic involvement. Strong suggestion is given and augmented when necessary by faradic stimulation of the muscles of the throat. As a rule complete relief of the aphonia has been obtained in the course of two or three treatments. Our most difficult cases have been those who have had a peculiar grunting type of speech rather than a true aphonia. This condition might more appropriately be called "hysterical dysphonia." This has usually become so deeply ingrained that an actual habit has been established of talking in this peculiar way.

In the meantime, the rest of the interview is taken up with delving into the history to determine the psychogenic factors responsible for the condition. In our experience sex has not played the dominant rôle. A very frank discussion with the patient is often conducive to a marked change in the patient's attitude toward his own problems. I try to get the patient to view his own condition from an impartial angle and will frequently ask him to give advice to someone else under the same conditions. It has usually not been necessary to resort to intensive psychoanalytic measures because the aphonia has most often followed close upon the precipitating situations.

As a rule our results in the treatment of hysterical aphonia have been excellent. In 1 or 2 cases seen within the last two or three years where relief of the symptoms has not occurred promptly, prolonged psychoanalytic treatment in other hands has also been unsuccessful. Best results are obtained in cases where the aphonia has been present but a short time. As already stated, those cases with the grunting or "bearing-down" type of speech are the most resistant, and particularly so if the condition has been present for months or years prior to therapy.

## CLINIC OF DR. ROY W. MOHLER

METHODIST HOSPITAL

---

### GONORRHEA IN WOMEN

I SHALL outline in this discussion some important points in the diagnosis and treatment of gonorrhea in women. Theoretic consideration will be avoided as much as possible so that this outline may serve as a safe and practical guide which can be followed by every physician who would undertake treatment of this important and serious condition. Gonorrhea of the internal genitalia will not be considered except in a prophylactic way and no thought will be given to gonorrhea in the preadolescent female.

#### ACUTE GONORRHEA

Gonorrhea may be an acute diffuse infection of the external genitalia when observed early in its course, or it may be a latent or chronic infection when observed late in its course. The acute stage of gonorrhea is usually easy to diagnose by a complete history taken from the patient or her consort, and an examination of the parts affected. Very often the patient suspects the condition and will tell you the source of her infection. The usual history is that exposure occurred from one to seven days before the symptoms were observed.

The symptoms of acute gonorrheal infection are often mild and not characteristic. There is some irritation about the external genitalia with burning and itching; if the urethra is infected there will be some dysuria; if the Bartholin's gland is infected there may be pain. A vaginal discharge may be present, but it has very little significance so far as a specific symptom is concerned. The symptoms may be so transitory that they have escaped the notice of the patient unless something occurs which calls her attention to her slightly unusual condition.

The examination of the patient is the most important part of the consultation. Before the description of the examination is given, I shall discuss briefly some of the habits of the gonococcus and the reaction which it produces in its host.

The gonococcus is a gram-negative diplococcus first described by A. Neisser in 1879. It is recognized in smears taken from the infected areas when stained by the Gram technic or some modification of it. The smears contain pus cells and the gonococci appear as two bodies like coffee beans with opposing flat surfaces with some organisms grouped inside of the pus cells and others free in the smear. The intracellular organisms are most significant.

The habit of the gonococci is to thrive on moist epithelial surfaces of the columnar type. For this reason the generalized infection about the genitalia persists for only a short while and usually complete subsidence of it has occurred within two or three weeks. The infection finally localizes in the urethral glands, Bartholin's gland, and the endocervix. Because these glands and the endocervix are lined by columnar epithelium, and because the areas drain badly, the infection persists indefinitely in them.

**Examination of the Patient.**—The patient is arranged for gynecologic examination on a suitable table. The bladder should have been emptied before the examination is undertaken. By this means the urethra will have been cleared of epithelial cells and degenerated pus cells. With good light the vestibule of the vagina is examined for any evidence of infection. Skene's tubules, the urethra, and Bartholin's ducts are minutely inspected, and after a thorough investigation of the parts, the secretion is removed from the vestibule of the vagina and from the urethral glands, and transferred to a clean glass slide by means of a wooden or metal applicator. The applicator should not be wrapped with cotton because of the confusion which the cotton fibers may cause in the study of the smear. These stained smears are studied at the time of the examination by the physician himself, or under his personal supervision. The presence of pus cells in smears taken from these areas is very significant of a gonorrheal infection either acute or latent, and if the examination is done carefully, the gonococci will almost surely be found. Many organisms

will be seen if the infection is recent, and only a few if the infection has been of long enough standing to have limited itself. If the gonococci are found in smears from the vestibule of the vagina and urethra, no further examination is necessary to make the diagnosis, and a more complete examination may spread the infection from the external genitalia to the endocervix which may be free of the infection.

**Treatment of Acute Gonorrhea.**—The treatment of acute gonorrhea is based on two premises, the first to manage the patient so that her infection will localize in the urethral glands, the endocervix, and Bartholin's gland; the second, to prevent so far as possible the extension of the infection to the fallopian tubes and the pelvic peritoneum. These aims may be accomplished usually by the following plan: a simple sedative should be given the patient, such as phenobarbital,  $\frac{1}{4}$  grain, and sodium citrate, 30 grains, every four hours; this mixture will alkalinize the urine and prevent some of the discomfort of which she may complain. Local treatment should consist of keeping the parts clean with some mild antiseptic soap and a vaginal douche of bicarbonate of soda (tablespoonful to 1 quart of warm water) once or twice daily. The douche should be given with the patient in the supine position with her hips slightly elevated and the water container placed 24 inches above her body. High-pressure douches are absolutely to be avoided. Specific directions should be given the patient to avoid all types of physical exertion or activity which would increase intravaginal pressure, such as coitus, dancing, swimming, diving, heavy lifting, and sexual stimulation. Topical applications of antiseptics to the infected areas should be avoided because of the danger of causing an extension of the infection to the internal genitalia, and because the antiseptics may inhibit the natural reaction of the tissue to the infection. Our aim in the management of these patients is to aid them and their own forces to overcome the acute infection. Good food, plenty of rest, and thorough elimination from the bowel are a necessary adjunct to this routine.

After a few weeks or longer of this routine, the acute infection will have become latent, the symptoms will have subsided, and the patient will not be conscious of her trouble.

In treating acute gonorrhea in women as outlined, we have recognized that it is essentially a self-limited infection and that our whole problem in the acute stage is to make the diagnosis, and to prevent as far as possible the extension of the infection to the internal genitalia.

### LATENT OR CHRONIC GONORRHEA

Latent or chronic gonorrhea is the type of infection which is most often seen. It is the term used to describe the infection after it has localized in Skene's tubules, urethral glands, Bartholin's gland, and the endocervix. The infection in these focal areas may persist indefinitely unless very active means are used to destroy it and, as long the infection persists, the patient is infectious to herself and to her consort.

**Diagnosis.**—The diagnosis of latent gonorrhea is quite difficult at times, especially when there is no known background of an acute infection. Smears should be made of the secretions taken from the urethra and from the cervix after the bladder has been emptied. To obtain smears from the urethra, it is massaged vigorously against the under surface of the symphysis and the expressed secretion transferred to a glass slide. If no organisms or pus cells are observed in the smears taken at the first examination, it should be repeated in twenty-four hours. Very often the trauma produced by the first examination will cause enough tissue reaction so that twenty-four hours later organisms or pus cells can easily be discovered. The presence of pus cells in the smears taken from the urethra is very significant of a latent gonorrheal infection and if one is persistent enough and thorough in examining the smears, gonococci are almost sure to be seen. Smears of the secretion from Bartholin's gland should also be secured and studied in the same manner.

The smears from the cervix should be taken with the utmost care. The cervix is exposed and all of the vaginal secretion gently cleaned from the portio, and the secretion from the cervical canal transferred to a glass slide by means of an unwrapped wooden applicator. The presence of pus cells in the smears indicates an endocervicitis which may be gonorrheal in origin. The gonococci are sometimes quite difficult

to find in the latent cases, but usually with care an occasional organism can be discovered. A good working premise is that a latent endocervicitis which accompanies a latent infection of the urethral glands is gonorrheal and the infection must be treated accordingly.

**Treatment.**—The Skene's tubules and the urethral glands are isolated with small probes and located very carefully before anesthetizing the urethra. A cotton-wrapped applicator saturated with a 10 per cent solution of cocaine hydrochloride is then applied to the urethral canal for five minutes. After the urethra has been properly anesthetized either a small tip cautery, or the electrode of a diathermy generator, is inserted into the isolated tubules, and each tubule is then coagulated. Complete healing of the coagulated area occurs in about twenty-one days after which a careful search for other foci about the urethra should be made and, if any are found, destroyed in the same manner.

At the time of the treatment of the urethra, the cervix is exposed and the infected endocervical tissue is destroyed. This may be accomplished by simple cauterization, coagulation, or endocervical resection. No anesthetic is required for cauterization or tissue coagulation of the cervix; however, an anesthetic is necessary for endocervical resection. Cauterization of the endocervix is by far the most easily accessible means of treatment but does not always seem to be so adequate as the other procedures. The reason, perhaps, is that not enough of the endocervical tissue can be destroyed without the occurrence of stenosis. Tissue coagulation seems to be a very satisfactory method. The electrode should be about 2 mm. in diameter; the current used should be adjusted so that carbonization and too deep destruction of tissue do not occur and the whole circumference of the cervical canal coagulated for about three quarters of its length. Endocervical resection may be undertaken and accomplished by the method described and popularized by Hyams, or it may be done by the operation described by Sturmdorf. Both of these methods are effectual if properly executed. They require, however, the facilities of an operating room and a general anesthetic, and certainly in most instances the other procedures will be quite as satisfactory.

The treatment of Bartholin's gland when it becomes necessary is sometimes a difficult problem. As a rule an abscess develops which must be incised and drained. If the whole of the gland has been destroyed by the infection, the area closes by granulation and no residual infection remains. If part of the gland remains, however, after the infection and the duct is closed, another abscess may form or a Bartholin's cyst may develop.

After destruction of the focal areas of infection, the patient should be instructed to carry out the same routine as prescribed for acute gonorrhea. The treated areas should be examined once or twice weekly, and if the slough seems to be preventing drainage of the parts, it should be separated very carefully.

A profuse offensive discharge follows these treatments in about four days, and some bleeding may occur when the slough separates. These symptoms may persist for ten days, and may cause the patient considerable anxiety. They are, however, the natural sequence of the treatments and can be managed usually without difficulty by warning her to anticipate them.

Complete evolution of the treated areas occurs in about four weeks. The treated Skene's tubules and urethral glands are replaced with fibrous tissue and their location is covered with squamous epithelium. The destroyed endocervix is replaced largely with squamous epithelium of the vaginal type. During evolution of the treated area of the cervix, there is a potential danger of stenosis occurring. This, however, does not occur frequently unless the treatment has been too vigorous or of a fractional type. If it should occur, its management becomes a problem which cannot be considered here.

**Diathermy Treatment.**—Diathermy treatment to increase intravaginal temperature must be mentioned as a means of treating endocervical infections. The methods are varied and some have considerable merit. The so-called "Elliott douche" and the short-wave diathermy machine with a special vaginal electrode are among the procedures used for this purpose. These are special appliances, however, and their use in the treatment of latent gonorrhea is not sufficiently standardized to be outlined for general use.

## PROOF OF CURE

To know when patients are cured and when it is safe for them to resume sexual relationship is the most important obligation one assumes in the management of gonorrhea in women. The disease can be cured and we must have some standard for proof of cure. The conventional standard for proof of cure based on the absence of the gonococci in three sets of smears taken at different intervals is very unreliable because occasional organisms, which could easily be missed in a very careful examination of smears, might well be responsible for a new infection in the individual or her consort. Cultures for the gonococci are not practical because of the contaminating organisms in the material secured for culture. The complement-fixation test is not sensitive enough to determine lower genital infection.

The method to determine cure, which is applicable in most cases, is one which I have used for a long period of time in my own work. I have been able to check on it a number of times and have come to regard it with considerable confidence. The method is based on the premise that the secretion from a noninfected urethra, Bartholin's gland, or cervix contains no pus cells. The reaction of these areas to the gonococci is an inflammatory one, and the secretions will therefore contain pus when infection is present. Smears are made at intervals of the secretions taken from these focal areas with considerable care, and each smear is examined for pus cells. If the smear contains pus cells, I presume that the patient is not cured, and further treatment and observation are necessary. Conversely, I presume that if pus cells are absent in the smears taken from these areas, no inflammation is present and the patient is no longer infectious. This whole course of treatment and observation will require considerable time, very often six months or more.

## CONCLUSIONS

I have outlined methods of treatment of gonorrhea in women. They are based on the following conceptions:

1. That the acute diffuse infection is self-limited.
2. That infection of the fallopian tubes and pelvic peritoneum can be prevented in most instances if no active treat-

ment is undertaken in the acute attack and if the patient is directed to avoid physical activities which increase intravaginal pressure.

3. That the focal areas of infection can be destroyed in latent gonorrhea.

4. That the absence of pus cells in the secretion from the lower genital tract is the best proof that these patients are no longer infectious and therefore are cured.

### PRACTICAL ASPECTS OF VITAMIN B DEFICIENCY

RECENT investigation of vitamin B deficiency carried out in this clinic has yielded information of importance to the practicing physician. From experience obtained in such study it is believed that a moderate deficiency of vitamin B is by no means rare; that clinical evidence of such deficiency can be recognized as a characteristic syndrome, and that the factors which predispose to the development of such deficiency are many and more varied than previously realized. Most of the information concerning the properties and functions of vitamin B has been obtained in the chemical and biologic laboratories and it is from these sources that the ultimate understanding of its physiologic rôle will come. It will be a long time, however, before this type of information is available in such form as to be of practical importance in clinical medicine and, in the meantime, it has seemed desirable to study the clinical aspects of vitamin B deficiency under as carefully controlled conditions as possible.

It is now known from biologic experiments that vitamin B is not a simple substance but is composed of several different fractions. The best-defined fractions are as follows:

Vitamin B<sub>1</sub>—concerned chiefly with the integrity of nervous tissue and probably acting as a catalyst in cellular oxidation processes.

Vitamin B<sub>2</sub> (G)—which is now subdivided into the following: (a) lactoflavine—necessary for normal growth, (b) vitamin B<sub>2</sub>—which prevents dermatitis in animals, and (c) pellagra-preventive factor—important in human pellagra.

Vitamin B<sub>4</sub>—concerned with the integrity of nervous tissue and probably important for normal bone-marrow function.

Knowledge obtained by a study of these separate fractions, made chiefly with animals, does not account for all of the functions of the vitamin B complex as observed in human beings and it is, therefore, with the rôle of the complete vitamin B\* complex that the clinician is now concerned. Much information has been circulated, chiefly by commercial houses, concerning the functions of vitamin B in humans. Many of these claims are extravagant and result in misapplied therapy. They arise from two general sources of error. First, results obtained from animal experiments, designed to test the effect of one of the separate fractions of vitamin B in a specific animal, have been applied uncritically to human beings; secondly, erroneous impressions are often gained from inadequately controlled observations on patients. It is only through very careful control of the environment of the patient and through prolonged observation that any adequate new information can be obtained on nutritional subjects of this type. It is the aim of this communication to give briefly proved facts concerning vitamin B deficiency in humans and to show by the presentation of certain representative cases how this information has been of assistance in treatment of patients. These observations have been confined to adults.

#### CLINICAL MANIFESTATIONS OF VITAMIN B DEFICIENCY

Symptoms and physical signs of mild vitamin B deficiency have been ascertained<sup>1, 2</sup> through prolonged study of patients subsisting on a diet of known composition. The changes encountered were referable chiefly: (1) to the gastro-intestinal tract; (2) to the nervous system; (3) to the blood and, in certain instances, (4) to the cardiovascular system.

1. **Gastro-intestinal Phenomena.**—The tongue is usually involved first, becoming sore sometimes without alteration in appearance, or there may be redness or loss of papillae unaccompanied by unusual sensation. Changes in the tongue have been noted as early as twenty-one days after beginning a diet deficient in vitamin B and have always preceded the

\* The term "vitamin B" is used in this communication to denote the entire B complex; individual fractions are referred to separately

development of other gastro-intestinal symptoms which are, characteristically, heart burn, a sense of fulness in the abdomen, loss of appetite and either constipation or diarrhea. These symptoms are accompanied by roentgen evidence of altered tone in the gastro-intestinal tract, the stomach becoming atonic and the small intestine displaying irregular areas of increased and of decreased tone. No characteristic alteration in the gastric acidity has been demonstrated. The absorption of protein from the intestinal tract has been studied in one patient and evidence of impairment obtained. Other investigators<sup>3</sup> have associated ulceration of the gastro-intestinal tract with deficiency of vitamin B. There is convincing evidence<sup>4</sup> that ulceration of the intestinal tract takes place in animals subsisting on a diet deficient in vitamin B, but, although manifestations of deficiency certainly are frequent in patients suffering from such conditions as colitis, it is difficult to be certain whether destruction of the intestinal mucosa is the result or the cause of the deficiency.

**2. Neurologic Phenomena.**—Paresthesias, particularly in the lower extremities, are an early complaint. Unless the deficiency is corrected these are followed by objective neurologic signs, the earliest of which is impairment of vibratory sense in the toes. The duration of the perception of vibration is at first decreased and later the sensation is lost.

Susceptibility to fatigue is an early symptom which appears at approximately the same time that paresthesias are first felt and changes noted in the tongue.

**3. Hematologic Changes.**—It has been possible to demonstrate alterations in the peripheral blood indicative of impaired bone marrow function in pregnant women<sup>2</sup> whose consumption of vitamin B was inadequate to meet the requirements of late pregnancy. The anemia resembled in every important respect the macrocytic anemia of pernicious anemia, sprue<sup>6</sup> and tropical macrocytic anemia.<sup>7</sup>

Ecchymoses without a history of trauma are frequently seen especially in the lower extremities.

**4. Edema and Cardiovascular Phenomena.**—Edema has been a prominent finding in the patients studied. It is not accompanied by cardiovascular or renal changes sufficient to explain it, and although, in certain instances, associated

with decreased serum protein, it is not strictly dependent on the serum protein level.

Cardiovascular changes are variable and never striking. The majority of patients complain of dyspnea on exertion and a certain number of them have shown a persistent tachycardia which has been associated with roentgen evidence of prominence of the pulmonary artery. There are no characteristic electrocardiographic changes. The marked cardiovascular signs in severe deficiency, *i. e.*, loss of peripheral vascular tone, hypotension and right-sided heart failure,<sup>8, 9</sup> are well known but should not be expected in cases of mild deficiency.

There are at present no satisfactory clinical tests<sup>10, 11</sup> which indicate the presence of early vitamin B deficiency, and the physician must, therefore, make the diagnosis from the manifestations listed above. It is apparent that no one of these indicates specifically the presence of deficiency, but it is, rather, the occurrence of the syndrome as a whole which suggests the condition. The clinician should be cautioned against attributing isolated phenomena to deficiency of this nature since it has been our experience that, although the severity of the different manifestations varies among individuals, no manifestation, later satisfactorily proved to be due to vitamin B deficiency, has occurred entirely independently of the others.

#### REQUIREMENTS FOR VITAMIN B

The vitamin B requirement of man varies according to certain known factors and also to some as yet unidentified ones. Thus a diet which may be adequate for one man will be quite inadequate for his neighbor, depending upon individual requirements. For this reason, in order to determine the likelihood of a person developing vitamin B deficiency, although it is necessary to know the approximate vitamin content of the diet, such knowledge alone will not suffice.

The minimum vitamin B requirement of a normal individual theoretically varies directly according to his weight and to his total metabolism.\* Thus if a man's weight and his basal metabolic rate remain constant, his vitamin B require-

\* The Cowgill formula<sup>12</sup> by which the theoretical vitamin B requirement may be calculated in terms of milligram equivalents of vitamin B (see below) is: vitamin B calories = 0.0000284 Gm.

ment will vary directly according to the number of calories he eats every day. These theoretical requirements have been corroborated by a study of the diet of alcoholics showing signs of deficiency<sup>13</sup> and by observation of a group of pregnant women whose dietary content of vitamin B was known.<sup>2</sup> In these women signs of deficiency developed when increase in weight resulted in theoretical requirements for vitamin B which exceeded the dietary intake. It has been found, also, that pregnant women who display a predilection for high caloric foods which are low in vitamin B, and so increase their caloric intake excessively, are predisposed toward the development of vitamin B deficiency (Case I). There is some evidence,<sup>1</sup> also, that if the chief source of calories is in carbohydrate the patient is more likely to develop deficiency than if the fat content of the diet is high. For some as yet unexplained reason fat spares the vitamin B,<sup>14</sup> permitting the more effective use of a small quantity of the vitamin.

The normal individual's minimum vitamin B requirement can be determined with fair accuracy; the optimum is less well defined. From animal experiments<sup>15</sup> it may be inferred that this is somewhere about five times the minimum and it has been our experience that the average person who has shown signs of vitamin B deficiency, but who is otherwise normal, can be relieved of deficiency and maintained in excellent health by this dosage.

There are many factors which increase the individual's vitamin B requirement above the normal and predispose him to the development of deficiency. Thus anything which increases the basal metabolic rate: hyperthyroidism (Case II) or fever will increase the need for vitamin B. Excessive muscular work, by increasing the total metabolism, increases the vitamin B requirement. Excessive caloric intake or excessive carbohydrate intake, as noted above, will increase the demand for vitamin B. Unusual gain in weight will result in evidences of deficiency if the vitamin content of the diet is not increased proportionately. This is probably the chief factor in the increased demand for vitamin B during pregnancy although altered endocrine function may play a rôle in some as yet unexplained way. The fact that evidence of vitamin B deficiency does not occur more frequently among the mal-

nourished is probably due to a combination of low total caloric intake and reduced body weight. It has been our experience that age plays some rôle in altering the vitamin B requirements. Elderly people, especially women, frequently show evidence of deficiency when the diet is apparently adequate (Case III). Whether this is a failure of absorption from the intestinal tract or is associated with some altered endocrine function is as yet undetermined. The effects of surgical procedures upon the development of signs of deficiency have been of particular interest to us. We have noted frequently that certain patients, who preoperatively show few or no signs of vitamin deficiency, following operation develop frank deficiency. There are several possible explanations for this fact. Fever increases the vitamin B requirement and in an individual whose vitamin intake has for any reason been impaired prior to operation, fever occurring postoperatively may result in very rapid development of deficiency, particularly if the intake of food is inadequate during this time. Thus, surgery of the gastro-intestinal tract is most often followed by evidences of vitamin B deficiency, the subjects of such surgery frequently having had a minimal vitamin intake prior to operation, *viz.*, pyloric stenosis patients, or having suffered failure of absorption of the vitamin through prolonged diarrhea: cases of colitis (Case IV), terminal ileitis, tuberculosis, etc., and such surgery often being followed by prolonged periods of inadequate food intake.

Decreased absorption from the intestinal tract will result in deficiency even in the face of adequate vitamin intake. Any prolonged diarrhea, regardless of the cause, is likely ultimately to result in deficiency. Any decrease in the available absorbing surface of the intestine will produce the same result. Alteration of gastro-intestinal secretions may influence the efficiency of absorption of vitamin B. We have noted that patients with achlorhydria frequently show evidence of deficiency even when the dietary intake is adequate (Case III).

#### SOURCES OF VITAMIN B

1. **Dietary.**—It is important that the clinician know the chief dietary sources of vitamin B. As has been pointed out, however, the vitamin content of the diet does not alone deter-

mine whether a given patient will develop vitamin B deficiency. A casual analysis of the diet may, therefore, lead to an erroneous impression unless the other factors which may influence the development of deficiency are kept in mind. It should be emphasized also that the concentration of the vitamin in a given food is important and simple qualitative analyses are often misleading. For example, while dried milk is an excellent source of vitamin B<sub>1</sub>, in whole milk the concentration of the vitamin is reduced to one seventh of that in the dry state and milk as ordinarily consumed, therefore, becomes a relatively poor source of the vitamin. It is important also to realize that the vitamin content of foods varies, in the case of animal foods, according to the diet of the animal and, in the instance of vegetables, according to the soil and atmospheric conditions. The vitamin B content of yeast, for example, varies enormously depending upon the type of yeast and the conditions under which it is grown. For these reasons it is desirable, when vitamin B deficiency is suspected from clinical evidence, to administer the vitamin in the form of preparations of tested potency.

The chief dietary sources of vitamin B may be found listed in detail in various texts,<sup>12, 16</sup> but if the following foods are kept in mind as the major sources of vitamin B in the average diet, they will serve as a fair working basis: liver, pork, kidney, beef, salmon, eggs, nuts, oatmeal, tomatoes, asparagus, artichokes, lima beans. Yeast and wheat germ are, of course, the richest sources of vitamin B, but since they are rarely included in the average diet they can hardly be considered dietary sources. In general, the various fractions of the vitamin are found in the same foods with the following exceptions: liver is an excellent source of vitamins B<sub>2</sub> and B<sub>4</sub> but contains negligible quantities of vitamin B<sub>1</sub>; egg white is also rich in B<sub>2</sub> without demonstrable amounts of B<sub>1</sub>.

The ideal diet, then, from the standpoint of vitamin B requirement is one which contains the calculated normal total number of calories (approximately 20 calories per pound for a person engaging in moderate activity), an average normal intake of carbohydrate (60 per cent of total caloric consumption to be derived from this source) and sufficient vitamin B to supply five times the minimum requirement. This latter

figure can be calculated from the Cowgill formula but in general will be covered if the individual consumes liberal quantities daily of at least three of the rich sources of vitamin B listed above.

**2. Special Sources.**—As has been stated, if vitamin B deficiency has developed as indicated from the clinical signs, it is wise to employ immediately one of the special sources, the potency of which has been ascertained.

Much use is made of the term "units of vitamin B" in advertising commercial sources of the vitamin. In determining the dose of these substances it is important to know the value of the units in which the potency of a given preparation is reported. The "Sherman unit"\* is the one most frequently employed and refers to the amount of special vitamin B<sub>1</sub> or B<sub>2</sub> preparations necessary to maintain normal growth in rats.<sup>17, 18</sup> Although, as has been seen from the foregoing discussion, it is impossible to make any accurate generalization concerning the amount of vitamin B required by patients, it can be said that probably a safe minimum amount to include in the diet of the average adult is not less than 1000 Sherman units† and the optimum will be approximately five times that amount. The special sources are as follows:

(a) *Yeast*.—This is the most adequate source of the B complex. There are many commercial preparations of yeast on the market. In selecting one of these the clinician should remember that brewer's yeast is a very much more potent source of the vitamin than baker's yeast and thus a smaller

\* Other units sometimes employed in listing the potency of vitamin B preparations are:<sup>12</sup>

1. "Pigeon unit"—the amount of B<sub>1</sub> necessary to cure pigeons of polyneuritis. This unit contains ten times the amount of B<sub>1</sub> in the Sherman unit

2. "International unit"—the amount of vitamin B<sub>1</sub> contained in 10 mg of standard substance kept at the National Institute for Medical Research, London. This unit contains four times the amount of B<sub>1</sub> in the Sherman unit

3. Cowgill milligram equivalent—the amount of B<sub>1</sub> contained in 1 mg of a standard yeast powder. One milligram equivalent contains one fifth the amount of B<sub>1</sub> in a Sherman unit.

† Sherman units have been worked out only for vitamins B<sub>1</sub> and B<sub>2</sub>. The dose of a substance should be calculated so that a minimum of 1000 units of either fraction is given. In such a dose it can be assumed that other fractions are included in adequate minimum amounts unless the substance is known to be poor in some fraction.

quantity of material from this source will answer the patient's need.

The following brewer's yeast preparations have been used extensively in experimental work and their potency in all essential fractions of vitamin B assured:\*

1. Yeast-Vitamin Powder (Harris).—A minimum dose of this substance is 5 Gm. and the probable average optimum is 25 Gm. or approximately 3 level tablespoonfuls daily.†

2. Vegex (an autolyzed yeast preparation known also as Marmite).—A minimum dose of this substance is 40 Gm., or 5 teaspoonfuls daily.

(b) *Wheat Germ*.—This substance is, next to yeast, the most complete source of the B complex. It is, however, richer in vitamins B<sub>1</sub> and B<sub>4</sub> than in vitamin B<sub>2</sub>. For this reason, when used in cases that show evidences of deficiency it is wise to employ a supplement which is rich in vitamin B<sub>2</sub>.

The wheat germ preparations which have received experimental investigation are:

1. Bemax—40 Gm. or 9 tablespoonfuls of this substance are required daily to supply the minimum of 1000 Sherman units of vitamin B<sub>1</sub>.

2. Vitavose—76 Gm. of this substance are required daily to supply the minimum of 1000 Sherman units of vitamin B<sub>1</sub>.

(c) *Liver and Liver Extract*.—Liver is an excellent source of vitamins B<sub>2</sub> and B<sub>4</sub>. All extracts prepared for use in pernicious anemia contain these vitamins. Liver extract is equally effective when administered parenterally or by mouth but since it contains comparatively little vitamin B<sub>1</sub> this should be given separately.

Liver extract No. 343 (Lilly) has been used experimentally as an effective source of vitamin B<sub>2</sub>. When given orally 20 Gm. constitute the minimum dose. Intramuscularly 2 cc. of the standard extract daily have been effective but some patients require as much as 10 cc. daily to relieve signs of deficiency.

(d) *Vitamin B<sub>1</sub>* is now available in the pure, crystalline form. It is prepared by the Merck Company under the trade

\* The preparations referred to are those with which the writer has had personal experience and do not comprise a complete list of available materials.

† The approximate dose of these preparations is calculated on the assumption that they constitute the sole source of the vitamin.

name "Betabion" and by the Winthrop Company as "Betaxin." It is equally effective when administered intravenously or when taken by mouth; 0.5 mg. constitutes the minimum dose of this substance and the probable optimum is 2.5 mg. Although there is some evidence that certain neurologic lesions are relieved by the administration of this substance alone, in the present state of our knowledge it is unwise for the clinician to depend entirely upon this substance for relief of the manifestations of vitamin B deficiency.

(e) *Lactoflavine*.—This substance has been prepared in pure, crystalline form. It apparently contains a growth-promoting factor which is a component of vitamin B<sub>2</sub>. Like all the special preparations of separate elements of the vitamin B complex this substance is at present of value chiefly for experimental purposes and should not be employed by the clinician as the sole agent in the treatment of clinical deficiency.

When special sources of vitamin B are employed it is necessary to consider whether oral administration will be effective. If there is reason to believe that absorption from the gastrointestinal tract is impaired, or if the patient's requirement is so increased that he is unable to take the vitamin in sufficient quantity by mouth to meet his needs, then parenteral administration is indicated. Liver extract and crystalline vitamin B<sub>1</sub> administered parenterally to the same individual in adequate dosage probably will supply all the necessary fractions.

### CASE REPORTS

**Case I.**—V. W., twenty-one years of age, a white female, was admitted to the maternity ward on December 2, 1936, nine months' pregnant, complaining of easy fatigue, sore tongue, heart burn, headaches, dyspnea on slight exertion, edema of the ankles, and a sense of numbness in the toes. Blood pressure 132/100, pulse 85, red blood cells 3,220,000, hemoglobin 61 per cent (Sahli), serum protein 5.3 Gm. per cent. Urine: specific gravity 1.020, albumin 0, casts 0. There was marked edema about the ankles, tongue was red with some loss of papillae at the edges, vibratory sense was impaired over the toes. It was found that while the patient's diet had been quantitatively adequate her appetite had been excessive

and she had taken a preponderance of carbohydrate foods. She weighed 165 pounds, this being 13 pounds in excess of her normal weight for that period in pregnancy. She was put on a weighed diet of 3000 calories containing 300 Gm. of carbohydrate and given 30 Gm. daily of Yeast-Vitamin Powder (Harris). She improved steadily and was discharged on December 17, symptom free, without abnormal physical signs, blood pressure 130/80, pulse 70, red blood cells 3,980,000, hemoglobin 70 per cent, serum protein 6.4 Gm. per cent. Urinalysis was negative.

This case is presented as characteristic of a number of pregnant patients recently encountered in whom excessive gain in weight, excessive total caloric intake, or a preponderance of carbohydrate foods in the diet have resulted in the appearance of clinical signs which respond to vitamin B therapy. Certain of these signs sometimes resemble those of the so-called "toxemia of pregnancy." Further study of these two conditions is necessary to determine in how far there is a common etiologic factor.

**Case II.**—F. C., fifty-four years of age, a white female, was admitted to the surgical service on January 5, 1934. Onset of typical symptoms of hyperthyroidism in August, 1933, viz., tremors, sweats, weakness, loss of weight. In November she suffered an attack of "grippe" and, following this, in addition to the continued symptoms of hyperthyroidism, she began to complain of the following which were prominent symptoms on admission: anorexia, epigastric discomfort, alternating constipation and diarrhea, sore tongue, dysphagia, shooting pains in the lower extremities, swelling of the ankles, and considerable mental confusion. On admission blood pressure 116/42, pulse 120, weight 100 pounds (normal, 144), basal metabolic rate + 63 per cent, red blood cells 3,500,000, hemoglobin 62 per cent, serum protein 6.5 Gm. per cent. She was obviously extremely ill, irritational, showed evidences of marked weight loss. The tongue was very red, smooth and was extended with a coarse tremor. The thyroid was slightly enlarged and diffusely nodular. The heart was diffusely enlarged. Except for tachycardia there were no electrocardiographic changes. Ecchymoses were scattered over the lower extremities

and there was pitting edema about the ankles. Marked muscular weakness, increase in the tendon reflexes, ankle clonus, and aphonia were present. It was thought that she was too ill for surgery and there was some question whether, judging from the complicated symptomatology and physical findings, all of her difficulties could be attributed to hyperthyroidism. A neurologic diagnosis of amyotrophic lateral sclerosis was considered possible. On January 17 vitamin B therapy in the form of 30 Gm. daily of Yeast-Vitamin Powder (Harris) was begun. On January 24, improvement was noted and by February 16 the patient was very much stronger, appetite was good and gastro-intestinal symptoms, including diarrhea, had subsided. The tongue was normal in appearance. Edema was relieved. Pains in the extremities were no longer complained of, aphonia was completely relieved, and, except for continued muscular weakness and tremor, the neurologic findings were normal. The patient failed to gain in weight, however, and the typical signs of hyperthyroidism continued. The basal metabolic rate remained between  $+40$  and  $+60$  per cent. At this time, through a misunderstanding, vitamin therapy was withdrawn and by March 20 all of the findings originally noted had returned. All forms of standard medical therapy for the treatment of hyperthyroidism were given, including roentgen ray therapy, without improvement in the patient's condition. On April 7, 1934, right lobectomy was performed and on May 18, 1934, the left lobe was removed. Following these procedures the patient's basal metabolic rate became normal and, without further treatment of any kind, she quickly returned to normal in every respect. When last seen on May 21, 1936, she weighed 164 pounds and was entirely normal.

This case is presented to show the increased demand for vitamin B in hyperthyroidism as evidenced by the appearance of the typical clinical manifestations of vitamin B deficiency, which were controlled by administering vitamin B in adequate quantities, even though the basal metabolic rate remained elevated. When the metabolic rate returned to normal the patient remained free of evidences of vitamin B deficiency on an average intake of that substance.

**Case III.**—S. K., thirty years of age, a white male, was admitted to the medical ward on October 1, 1935. The patient had always been a "finicky eater," for the most part eschewing animal foods, but had remained essentially well until September, 1935, when he suffered what appeared to be an attack of acute gastro-enteritis. Diarrhea resisted all local therapy, however, and when admitted, he presented the typical picture of ulcerative colitis. From October to January all standard measures for the treatment of this condition were without success and by this time the patient had developed definite edema of the ankles and serum protein was 3.8 Gm. per cent. At this time the patient suffered an attack of acute appendicitis and at operation a ruptured appendix was removed. Almost immediately following operation he began to vomit, diarrhea increased and became bloody, edema became extensive. A prolonged febrile course ensued and on February 4 it was necessary again to operate for a pelvic abscess. Following this surgical procedure the vomiting became uncontrollable, edema increased still further, the tongue became red, smooth and sore. An erythematous dermatitis appeared on the dorsa of both forearms, he complained of pains in both lower extremities and his vibratory sense, at first impaired, was soon lost in both lower extremities. He appeared to be in a moribund condition. At this time vitamin B therapy was begun in the form of liver extract No. 343 (Lilly), 5 cc. intramuscularly daily; Yeast-Vitamin Powder (Harris), 21 Gm., and an especially prepared wheat embryo extract, 25 cc. (525 Sherman units), by mouth daily. Improvement began in two weeks at which time vomiting was controlled and the tongue became normal in appearance. Gradually the other signs subsided until, at the end of eight weeks edema was gone, serum protein was 4.2 Gm. per cent, neurologic examination was negative and there were no neurologic complaints. Dermatitis had subsided. There had been a gain in weight of 10 pounds and, except for some looseness of the stools, he was apparently normal. All vitamin therapy was withdrawn and on May 24, 1936, he was allowed to return home on his regular diet. He remained well until June when he lost his appetite and gradually all of the symptoms and signs previously noted returned. He was seen in the hospital again in September at which time his

condition was as described in February. Before therapy could be instituted one of the ulcers in the colon perforated and the patient died of general peritonitis.

This case is presented to show that in an individual, whose vitamin intake had apparently been just adequate to meet ordinary requirements, the occurrence of an acute diarrhea, accompanied by decreased absorption from the intestinal tract, was sufficient to precipitate a state of deficiency. This deficiency did not become definite, however, until following surgical procedures which were accompanied by decreased intake of food and by fever. At that time the characteristic evidences of vitamin B deficiency became manifest. Parenteral and oral administration of vitamin B resulted in slow improvement. The patient remained well until vitamin therapy was withdrawn when, probably due to a combination of inadequate vitamin intake and inadequate absorption, the result of permanent damage to the intestine, a state of deficiency again developed. It is, of course, a matter for speculation whether this man could have been kept in good health by continued administration of vitamin supplements but from experience which we have had with subsequent cases of colitis, it would seem wise to continue this form of therapy indefinitely.

**Case IV.**—F. S., sixty-one years of age, a white female, has been seen in the Gastro-Intestinal Section at intervals since 1933. She had complained of vague epigastric discomfort for about fifteen years prior to coming to the Section. For the past six years she had complained of weakness, vertigo, soreness of the tongue and recently of a feeling of numbness and cramps in the calves of the legs at night. She had noticed slight swelling of the ankles in the last few months, dyspnea and a peculiar pallor of the skin. These symptoms, though not incapacitating, made it difficult for her to do her daily work. Blood pressure 112/80, pulse 65, red blood cells 4,600,000, hemoglobin 86 per cent, serum protein 6.8 Gm. per cent. On examination, waxen pallor of her skin was noted and there were several ecchymotic areas scattered over the lower extremities. There was definite edema about the ankles. No abnormalities were detected on examination of the heart. Electrocardiogram was normal except for the bradycardia.

The tongue was red and smooth. Gastric analysis revealed achlorhydria with histamine. Roentgen examination of the gastro-intestinal tract disclosed no abnormalities. Vibration sense was not perceived in the lower extremities. She was first given Yeast-Vitamin Powder (Harris), 30 Gm. daily, in October, 1933. Improvement began in two weeks and at the end of the month she was relieved of the symptoms which had brought her to the hospital. The tongue became normal in appearance, edema disappeared and vibratory sense returned in the lower extremities. The yeast has been continued to the present, with intervals in which it has been withheld always being accompanied by a return of the original symptoms. As long as the yeast is taken in the above dosage the patient is maintained in average good health. There has been no alteration in gastric acidity during the period of observation.

This patient is characteristic of many of her age and sex whom we have encountered with similar symptomatology and who have been relieved by the therapy employed in this instance. In many of these patients achlorhydria has been a finding, although not invariably so.

## CLINIC OF DR. F. WILLIAM SUNDERMAN

DEPARTMENT OF RESEARCH MEDICINE AND THE WILLIAM  
PEPPER LABORATORY OF CLINICAL MEDICINE, UNIVERSITY  
OF PENNSYLVANIA

---

### ESSENTIAL PENTOSURIA

To diagnose pentosuria correctly is a matter of practical importance since patients presenting this anomaly are frequently mistreated for diabetes mellitus. Recent studies would indicate that the occurrence of pentosuria may not be as exceedingly rare as it had been formerly presumed. Individuals with pentosuria present no known symptoms by which the existence of this error of metabolism might be suspected, and the recognition of the condition depends entirely upon the response of a given urine to certain appropriate tests. Employing a simple test which contributes to the identification of the pentose, *l*-xyloketose, and which can be easily made in the course of the routine examination of urine, Englewitz and Lasker<sup>1</sup> were enabled in 1933 to add 12 cases of pentosuria to the approximately 100 cases which had been previously reported in the entire literature. Within the past year Lasker, Englewitz and Lasker<sup>2</sup> have extended their studies to include observations on 41 pentosurics. Moreover, these authors report that Blatherwick has discovered 31 additional cases of pentosuria in the analysis of 130,985 specimens of urine submitted to the Metropolitan Life Insurance Company for examination. A recent discovery of pentosuria in a patient and in 3 other members of the patient's family has prompted us to comment briefly upon the studies which have led to the diagnosis of this condition.

#### SUMMARY OF THE HISTORY AND PHYSICAL EXAMINATION OF THE PATIENT

An eight-year-old Jewish girl was admitted to the University Hospital on Dr. J. C. Gitting's service because of burning

on urination and enuresis since infancy. The enuresis was so severe that the act of walking usually resulted in an incontinence of urine.

Physical examination revealed an essentially healthy girl about 20 per cent above her ideal weight. A cystoscopic examination showed a low-grade diffuse inflammation of the bladder mucosa and an abnormally enlarged and thickened internal sphincter. The diagnosis of mild diffuse cystitis of undetermined etiology and a congenital malformation of the internal sphincter was made.

After her admission to the ward it was found that practically every specimen of her urine examined reduced Benedict's solution. The concentrations of blood sugar, obtained after fasting and after the ingestion of glucose, were within the normal limits and the excretion of sugar appeared to be unaltered by changes in the composition of the diet. These findings led to an investigation of the nature of the urinary sugar, which was later identified as the pentose, *l*-xyloketose.

It may be noteworthy that the parents of the patient are first cousins and that one of her brothers is a deaf-mute.

The early literature of pentosuria has been reviewed by Garrod in his excellent monograph on "Inborn Errors of Metabolism."<sup>3</sup> In brief, the discovery of pentosuria came only a few years after the discovery of the existence of sugars of the pentose group. In 1887 Killiani showed that arabinose, the sugar obtained from gum arabic, which had previously been classified as a hexose contained only 5 carbon atoms in its molecule. Shortly afterward it was shown that xylose, the sugar obtained from wood, was also a pentose and that many vegetable structures contained polysaccharides of high molecular weight, known as pentosans, which on hydrolysis yield the aldopentoses, *l*-arabinose and *d*-xylose.

The first case of pentosuria was described by Salkowski and Jastrowitz<sup>4</sup> in 1892. Analyzing the urine of a morphine addict these workers coincidentally found that the urine contained a sugar the osazone of which had a melting point between 157° and 158° C. and was soluble in hot water, in contrast to the osazone obtained from glucose which had a higher melting point and was relatively insoluble in hot water. The crystalline structure of both osazones was similar. The

low melting point of the osazone suggested to these investigators that the sugar present in their patient's urine was a pentose.

As other cases were reported it was soon recognized that two types of pentosuria existed, an alimentary and an essential pentosuria. The alimentary type was found without any associated error of metabolism. Von Jaksch<sup>5</sup> demonstrated that when unfermented fruit juices containing arabinose, such as cider, were ingested in large quantities by certain individuals, the urinary excretion during the following twenty-four hours frequently yielded the pentose, arabinose. On the other hand, in essential pentosuria the excretion of the pentose was unrelated to the composition of the diet and the disorder occurred almost entirely in the Jewish race, and mostly in males.

Essential pentosuria is generally regarded as a harmless and symptomless condition. After reviewing the literature, Margolis<sup>6</sup> pointed out that of the 44 cases reported with adequate clinical histories up to 1929, approximately one fourth suffered from headaches and three fourths were psychoneurotic. Garrod in his studies suggests, however, that racial temperament and the fact that most of the individuals with pentosuria had been under treatment for diabetes might be contributory factors in accounting for psychoneurotic symptoms. There is no reason to believe that the presence of pentosuria decreases the span of life.

In the older literature almost every known pentose has been described as occurring in the urine of pentosurics. However, since Levene and La Forge's<sup>7</sup> studies in 1914 and Hiller's<sup>8</sup> studies in 1917, in almost all of the cases of essential pentosuria thoroughly studied *l*-xyloketose has been the pentose found, although racemic arabinose also has been reported. In alimentary pentosuria the responsible sugar is generally regarded as arabinose.

The source of *l*-xyloketose excreted in the urine is unknown. When xylose is injected into dogs about 65 per cent is excreted unchanged, whereas when *l*-xyloketose is injected only 8 to 14 per cent is excreted unchanged. From these experiments Greenwald<sup>9</sup> concluded that *l*-xyloketose can be metabolized in the body. Moreover, Englewitz and Lasker<sup>1</sup> fed a

pentosuric 5 Gm. of *l*-xyloketose isolated from his own urine and found that the amount of the pentose excreted within the twenty-four hours after the ingestion was only 0.5 Gm. more than the usual excretion. They concluded that an individual with pentosuria can either utilize or destroy *l*-xyloketose when it is administered by mouth.

Chemical theory demands the existence of 8 aldopentoses and their 4 corresponding ketoses (Table 1). Of the 8 aldo-

related to

*d*-glyceric aldehyde (+)

*l*-glyceric aldehyde (-)

pentoses 7 are known, *l*-xylose apparently having not been isolated. Of the ketopentoses, so far as we are aware, only *l*-xyloketose has been obtained in the pure state. It should be pointed out that the prefixes *d* and *l* given in Table 1 do not indicate the direction of optical rotation but refer to the spatial configuration of the molecule as related to the *d* and *l* forms of glyceric aldehyde.\* In the early literature confusion in terminology exists so that *l*-xyloketose is sometimes referred to as *d*-xyloketose. The signs + and - refer to dextro- and levorotatory properties respectively. Thus, for example, *l*-xyloketose is dextrorotatory.

In Table 2 are given tests by which pentosuria may be differentiated from glycosuria. The pentoses are not ferment-

\* It has been arbitrarily agreed upon to designate sugars with the grouping

able. The addition of HCl to pentoses yields furfural; on the addition of orcinol, furfural forms a green-black dye product. This test, known as Bial's dye test is useful as a qualitative test for the presence of pentose although it should be recognized that menthol, turpentine and other organic chemicals may also give the same reaction. The optical properties of the urine in pentosuria have not been reported with any degree of consistency. Most of the reports would suggest that the urine is optically inactive. However, Hiller's studies would indicate that if the urine be concentrated and if *l*-xyloketose be present, the optical rotation is to the right. Racemic arabinose is optically inactive and if present would not contribute to the optical rotation of the urine. The melting point of the purified osazone of *l*-xyloketose is between 156° and 160° C., whereas the melting point of the glucosazone is approximately 210° C. On boiling, both pentoses and hexoses reduce Fehling's or Benedict's solution; however, on heating to 50° C. for ten minutes only *l*-xyloketose will reduce the copper of these solutions. Bromination as described by Hiller may be used to differentiate between the aldose and ketose sugars. The ketoses are capable of reducing Benedict's solution after bromination, whereas the aldoses are not. The glucose tolerance curve is of the normal type in pentosurics; of the diabetic type in glycosurics, excepting in renal diabetes in which the glucose tolerance curve may be normal.

In 1933 Lasker and Englewitz<sup>10</sup> reported a simple procedure which should facilitate the recognition of essential pentosuria in office practice. These workers found that the addition of 1 cc. of urine to 5 cc. of Benedict's qualitative solution gave reduction at 50° C. within ten minutes, provided the urine contained the pentose, *l*-xyloketose, in at least 0.1 per cent concentration. None of the other sugars examined by them gave reduction within this interval of time; the closest was levulose which required twenty minutes at 50° C., and levulose is rarely found in urine. In Table 3 are given data taken from Lasker and Englewitz's studies indicating the periods of time required for the reduction of various sugars which they studied.

The urine of our patient reduced Benedict's solution within ten minutes when heated at 50° C.; was nonfermentable; gave a greenish color when treated with Bial's reagent, and yielded needle-like osazone crystals when treated with phenylhydrazine. Using Hiller's method the same amount of reduction of Benedict's solution was found after bromination of the sugar as before. Furthermore, a purified osazone was prepared which gave a sharp melting point at 158.7° C., thus identifying the sugar as *l*-xyloketose.

family of 6 individuals 3 children and possibly the mother were pentosurics.\*

\* The mother was uncooperative and refused to submit to further studies.

In clinical and insurance practice any individual whose urine reduces Benedict's solution and in whom the concentration of blood sugar is within the normal limits should be suspected of having either pentosuria or renal glycosuria. Support for the diagnosis of the former might be easily obtained by testing the urine for *l*-xyloketose according to the Lasker and Englewitz procedure.

## CLINIC OF DR. MARGARET CASTEX STURGIS

WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA

---

### TREATMENT OF MENORRHAGIA AND METRORRHAGIA IN THE ADOLESCENT

MENORRHAGIA and metrorrhagia are time-honored terms, the former meaning increase in amount or duration of uterine bleeding or both, at the regular interval; whereas the latter refers to uterine bleeding at times irrespective of the regular rhythm. Hemorrhage, in general, is an abnormal process except in the function of menstruation, when hemorrhage from the uterus occurs normally at relatively regular intervals. It is only when there are abnormalities in the quantity and rhythm of the menstrual flow that uterine hemorrhage takes the aspect of a pathologic process.

Recent advances in research concerning the physiology of menstruation has helped to emphasize the extreme complexity of the normal mechanism. Today menstruation is recognized as an endocrine phenomenon and this added knowledge has illuminated and assisted in the explanation of many problems concerned in its disorders.

In considering causative factors in abnormal uterine bleeding pathology in function as well as pathology in anatomy must be taken in account. Therefore causes are classified as: (1) constitutional, (2) local or organic, and (3) functional. In the adolescent, constitutional and functional causes are the ones of most interest; the constitutional because of their indirect effect upon the endocrine system and the functional because puberty and early adolescence mark a period of relative endocrine instability.

1. Constitutional diseases *per se* are as a rule associated with scanty periods. Amenorrhea is the more common observation. However, irregular and excessive flow does occur and profound anemia becomes a sequel. Excessive uterine bleed-

ing associated with pelvic pain necessitates the ruling out of tuberculosis of the fallopian tubes. Certain blood dyscrasias must be considered because so frequently uterine bleeding is the only outstanding symptom. Chronic thrombocytopenic purpura may manifest itself first in severe menorrhagia. Acute infectious diseases rarely cause uterine bleeding. Influenza is an exception in that it accelerates and aggravates the menstrual flow. Chronic valvular heart disease with its associated passive congestion of the pelvis may at times be a responsible cause. Nervous disorders must not be overlooked in the adolescent. Sudden shocks and severe frights have been known to precipitate profound uterine hemorrhage.

2. **Local or organic disorders** in the generative system are rarely observed as cause of abnormal uterine bleeding in the adolescent. Less frequently are we concerned here with uterine displacements, polyps, myoma, adnexal disorders, carcinoma and ovarian new growths. However, they must all be ruled out, even when studying an adolescent. Granulosa cell carcinoma of the ovary does occur in the young girl and even in children. Carcinoma of the uterus has been found in the immature woman, although it is a very rare finding. Pregnancy and its many disorders with bleeding must be considered.

3. It is with the **functional** causes we are most concerned. Under this classification fall all cases of atypical menstruation in an apparently normal, well young girl. "Functional uterine bleeding," more fittingly called "dysfunctional uterine bleeding," is the term used to refer to those disturbances in uterine bleeding, either menorrhagia or metrorrhagia, which have apparently no definitely demonstrable organic or constitutional conditions as a cause. This form of atypical bleeding is accepted now as due to a disturbance in the hormonal mechanism that controls normal menstruation. This type of bleeding may commence at puberty or may commence after one or several normal periods. Menstrual irregularities are noted as shortened interval, or change in rhythm with intermenstrual spotting of brownish discharge. Very profuse prolonged periods may be the beginning in some cases with only short intervals which may or may not be attended by a constant brown discharge. As a rule, these cases run a more or less mild and chronic course with anemia the outstanding

systemic manifestation. Fortunately, many cases spontaneously adjust themselves. However, others may and do assume a very grave course with profound secondary anemia.

Endocrinopathic evidences are absent in most of the dysfunctional uterine bleeding cases of adolescence. There is little evidence, if any, of hyperthyroidism or hypothyroidism. The girl may be either thin or fat and is usually a very normal feminine type.

In order to understand the rational of the treatment, a brief explanation of the accepted rôles of the endocrines as they influence both normal and abnormal uterine bleeding must be given. The pituitary gland, the ovaries and the uterus are necessary for menstruation. The anterior lobe of the pituitary body produces two known gonadotropic secretions, the follicle stimulating hormone (prolan A) and the luteinizing hormone (prolan B). These secretions act upon the ovaries which produce the estrogenic hormone (follicular hormone, theelin or estrin) and progesterin. The influence of this coordinate function is in turn exerted on the endometrium to bring about the cyclic changes which end in bleeding. Estrin dominates the first half of the cycle and stimulates proliferation of the endometrium. In normal states, under the influence of the luteinizing hormone of the anterior pituitary body, ovulation occurs and the ruptured follicle becomes a corpus luteum. Progesterin, a hormone of the corpus luteum, then takes control of the endometrium and the secretory stage ensues. What actually causes menstrual bleeding is not definitely understood.

Studies by Schroeder<sup>1</sup> and later by others have demonstrated that the ovaries in most dysfunctional uterine bleeding cases show a characteristic finding, namely, absence of corpora lutea and a persistence of unruptured graafian follicles. This is interpreted to mean a persistence of ovarian follicular hormone (estrin, theelin, folliculin) with absence of progesterin or the luteinizing hormone. Persistence of follicular hormone continues the proliferative state of the endometrium without the secretory influence of progesterin. This proliferative state results in a cystic hyperplasia of the endometrium. Bleeding occurs and the endometrium apparently is never completely shed. According to Schroeder this bleeding comes from superficial necrosis, the result of capillary thrombosis. Pankow<sup>2</sup>

and more recently Traut and Kuder<sup>3</sup> and others have demonstrated a lack of conformity to any single type of endometrium in all dysfunctional bleeding cases. Pathologic examinations show in addition to "cystic hyperplasia," "irregular maturation of the endometrium," and "defective shedding." Anspach and Hoffman<sup>4</sup> (1934) confirmed these findings and they were also borne out in a series of cases reported by Macfarlane<sup>5</sup> (1936). Hartman's<sup>6</sup> hypothesis, based upon experiments with monkeys, that bleeding *per se* is due to a special nongonadotropic hormone in the anterior lobe of the hypophysis may be the explanation. Novak<sup>7</sup> likewise agrees that whatever the factor is, it certainly seems in some way bound up with a disturbance in the balance between the two anterior pituitary hormones. An excess of the bleeding factor and a deficiency or absence of the lutein tissue and its hormone appear to go together. Wilson and Kurzrok<sup>8</sup> accept this theory and advance the hypothesis that this bleeding hormone is stimulated by the follicular hormone but inhibited by progesterin and that bleeding ensues when a certain concentration of follicular hormone is reached unless inhibited by progesterin.

All investigators, however, agree that an imbalance exists between the two ovarian hormones and that the ovarian governing principles of the anterior pituitary body play the important rôles and therefore constitute the main factor in the production of this disorder. What external or internal factors affect the pituitary gland to bring about this disorder in the menstrual cycle is not yet proved.

Other glands of internal secretion especially the thyroid have been known to be associated with excessive menstruation. What rôle they play other than an indirect influence is not explained.

**Diagnosis.**—Menorrhagia or metrorrhagia at puberty and during adolescence, although practically always due to disturbance of function, demands a general physical examination and a bimanual examination of the pelvic organs by rectum and abdomen. A blood count, urinalysis and basal metabolism must be done. In this manner rare cases of neoplastic, inflammatory or tuberculous diseases may be eliminated as well as postpregnancy disorders. Aspiration curettage in diagnosis had better be reserved for the mature woman.

**Treatment.**—*Constitutional and Tonic.*—If pelvic pathology or constitutional disease is found the treatment is directed toward the elimination of the pathologic condition. But in the absence of organic lesions treatment in the young should consist of all general measures for upbuilding the health. Time-honored employment of rest, hygienic measures, tonic treatment and iron administration between bleeding periods, must be employed. Oxytocic drugs, ergot and pituitrin, will temporarily diminish the bleeding but since there is no evidence to show that failure of muscular contractibility is a major cause, their usage is palliative. Attempts at increasing the coagulability of the blood may be accomplished by administration of large doses of calcium by mouth, intravenously or intramuscularly. Severe cases of excessive bleeding even necessitate blood transfusions, one or more. Blood of a pregnant donor has been advised. In adolescent bleeding cases, irradiation of the spleen has been effective in diminishing the bleeding and so temporarily bringing relief. Water moccasin venom has received attention in the treatment of dysfunctional uterine bleeding. This form of therapy attempts to diminish the permeability of the blood vessel walls. Peck and Goldberger<sup>9</sup> and Frank<sup>10</sup> report satisfactory results, but results at best are temporary. As said before, many cases of mild form correct themselves spontaneously or after certain constitutional and tonic aids. Others require the most painstaking study and treatment.

*Endocrine Therapy.*—Endocrine therapy in dysfunctional uterine bleeding cases consists in the administration of extracts of the corpus luteum, extracts made from pregnancy urine and placental extracts, and extracts of the anterior pituitary body. Since lack of progestin or inadequate amount is responsible in most cases, the treatment would seem to be directly substitutive. Potent extracts of the corpus luteum in sufficient dosage has not become commercially available because of the limited source of supply. Extracts which have gonadotropic effects have been made from the urine of pregnant women and from placenta. But because they appear not to be identical to the extracts of the anterior pituitary body, though having similar effects, they are called "anterior pituitary-like hormones." The source of supply is abundant, hence these ex-

tracts offer the best method of stimulative treatment. Antuitrin S (Parke, Davis), anterior pituitary-like hormone A. P. L. (Collip), follutein (Squibb), and other commercial preparations are on the market at the present time containing the gonadotropic fraction. Any one of these preparations have given good results when used in sufficiently large doses. Two hundred to 500 rat units must be given daily to bleeding cases. The dose is diminished as the bleeding ceases and the interval increases. Two hundred rat units are given twice a week after bleeding stops for an indefinite number of weeks, until the bleeding is controlled. Surprising results have been achieved with this form of therapy. Occasionally a period of prolonged amenorrhea may ensue, but this is not objectionable, especially if there exists a severe anemia. This permits time for the rebuilding of the blood and frequently the endocrine mechanism reestablishes an equilibrium. The exact method by which this anterior pituitary-like hormone controls dysfunctional uterine bleeding has not been definitely established. The control may be inhibitory on the bleeding factor since experiments have shown absence of effect on the endometrium. Anterior pituitary extracts have offered good results but not so effectively as the extracts of pregnancy urine and placental tissue.

One must not forget the coordinating influence of the other glands of internal secretion. The thyroid especially must be considered in cases with low basal metabolic rate and hypothyroid manifestations. Thyroid therapy in some cases has been attended by excellent results. The administration of insulin has produced favorable results in shortening the duration of bleeding in juveniles. Most of the good results as reported by Klaften,<sup>11</sup> however, were obtained in that group of women who had a hereditary history of diabetes or in those who later developed diabetes and in the underweight group.

*Surgical Treatment.*—Failure of endocrine therapy in the past and possibly impatience on the part of the patient or her family, has led to other more radical procedures. Persistence in treatment on the part of the physician and confidence in the physician on the part of the patient are two very necessary attributes for success in the treatment of adolescent uterine dysfunctional bleeding. The time-honored curettage which

was formerly done in those intractable cases has now come into its own probably more for its diagnostic than therapeutic usage. However, the fact that some cases are followed by recovery, places the procedure in the category of treatment as well. Occasionally repeated curettements are found necessary. Certainly in light of our present knowledge of the physiology the removal of the bleeding surface can only afford temporary relief. In adolescent bleeding curettage should be especially limited because of the psychic effect on the patient.

Novak<sup>12</sup> so highly regards the endometrium as the registering board of the two ovarian hormones that he emphasizes the importance of the microscopic study of the endometrium in all cases of menstrual disorder and considers more can be obtained by aspiration curettage concerning ovarian activity than from blood and urine hormone studies. This procedure, however, though very simple and can be done in the office without anesthesia, is hardly desirable except in intractable cases in the young adolescents.

Radical surgery in the young woman can only be considered in very grave cases. Resection of both ovaries, or removal of one ovary in order to diminish the amount of persisting follicular influence is attended by only temporary success which hardly justifies the procedure. Other more radical operations as bilateral oophorectomy, supravaginal hysterectomy or even fundectomy should have no place in the treatment of juvenile uterine bleeding except as a last resort in that occasional grave case.

*Radium Therapy.*—Because of the serious effect upon the child-bearing function, treatment by radium should be deferred. Small doses of radium—300 to 800 mg. hours of radium—will temporarily check the bleeding and may be used when endocrine therapy, curettage and constitutional aids do not control the bleeding. This will give a temporary cessation and the periods will return, at times normally, at other times atypically. Radium therapy may have to be repeated.

*x-Ray Therapy.*—x-Ray over the ovaries should be reserved as treatment for the woman near her menopause and therefore has no place in the treatment of the adolescent. Irradiation of the pituitary gland has been reported as giving immediate relief. Small doses of x-ray are said to bring about

increased pituitary activity with stimulation of the ovaries to normal function. This method of treatment has not, however, received universal accord and does present a method of treatment attended by too many dangerous possibilities to warrant its use.

To summarize the treatment of menorrhagia and metrorrhagia in the adolescent:

1. Constitutional and tonic aids chiefly by drugs directed toward the anemia, transfusion of whole or citrated blood in severe cases, and oxytocic drugs to control the bleeding.

2. Administration of extracts of pregnancy urine in large doses.

3. Curettage, even repeatedly, in intractable cases.

4. Radium in small dosages in those grave bleeding cases which will not respond to any other form of therapy.

# CUMULATIVE INDEX

- ABDOMEN, acute, general practitioner and, *July*, 1095  
 Abdominal angina, *Jan.*, 239  
     enlargements in children, diagnosis, *May*, 813  
 Acanthosis nigricans, *May*, 863  
 Acid intoxication in diabetes, management, *Jan.*, 16  
     regurgitation, dyspepsia and, *May*, 648  
     therapy, antiseptic, in urinary tract infections, *March*, 606  
 Addison's disease, skin manifestations, *May*, 862  
 Adenomatous goiter without hyperthyroidism in children, *May*, 834  
 Adolescent goiter, *May*, 832  
 Adrenals, obesity and, *Jan.*, 28  
 Agglutination test in tularemia, *May*, 858  
 Agranulocytic angina in childhood, *Jan.*, 105  
 Ainhum, *Jan.*, 252  
 Aleukemia, *March*, 357  
 Aleukemic leukemia in childhood, *Jan.*, 107  
     appendicitis and, differentiation, *Jan.*, 108  
     myelogenous leukemia, *March*, 353  
     myelosis, *March*, 354  
 Alkalosis, dyspepsia and, *May*, 669  
 Allergic factor in migraine, *Jan.*, 123, 139  
 Allergy, dyspepsia and, *May*, 670  
     food, *Jan.*, 119  
     studies in, *March*, 613  
 Amebiasis, treatment, *May*, 717  
 Amebic dysentery, *Jan.*, 159  
 Amyloid deposits in skin, *May*, 869  
 Amyloidosis, systematized, *May*, 869  
 Anemia, aplastic, in childhood, *Jan.*, 106  
     erythroblastic, *Jan.*, 97  
     from vitamin C deficiency, *May*, 746  
     hemolytic, congenital, in infancy and childhood, *March*, 401  
     of pregnancy, diagnosis, *July*, 1185  
     treatment, *July*, 1185  
     pernicious, *March*, 333. See also *Pernicious anemia*.  
 Anemic ulcers of leg, treatment, *Jan.*, 244  
 Angina, abdominal, *Jan.*, 239  
     agranulocytic, in childhood, *Jan.*, 105  
     pectoris, hypertension and, *July*, 1054  
 Anorexia, dyspepsia and, *May*, 649  
 Antepartum fetal death, diagnosis and management, *Jan.*, 300  
 Antiseptic acid therapy in urinary tract infections, *March*, 606  
 Aortitis, syphilitic, diagnosis of, *July*, 1013  
     pathologic physiology, *July*, 1015  
     treatment of, *July*, 1013, 1026  
     uncomplicated, prevention of, *July*, 1023  
 Aphonia, hysterical, diagnosis of, *July*, 1211  
     malingering in, *July*, 1211  
     treatment of, *July*, 1211  
 Aplastic anemia in childhood, *Jan.*, 106  
 Appendicitis, aleukemic leukemia in childhood and, differentiation, *Jan.*, 108  
     dyspepsia and, *May*, 660  
 Arms, paroxysmal attacks of pain in, heart disease and, *July*, 1009  
 Arrhythmias, cardiac neurosis and, *March*, 454  
     sinus, *July*, 1033  
 Arsenicals in urinary tract infections, *March*, 611  
 Arthritis, chronic, management of, in home, *March*, 511-524  
     in leukemia in childhood, *Jan.*, 101  
 Artificial pneumothorax, contraindications, *July*, 1200  
     danger signals, *July*, 1206  
     indications for and technic of, *July*, 1193  
     for terminating, *July*, 1208  
     management, *July*, 1207  
     pathologic considerations, *July*, 1197  
     physiologic considerations, *July*, 1194  
     use of apparatus, *July*, 1204  
 Ascites with heart murmur, *July*, 1008  
 Asthenia, neurocirculatory, *March*, 471

- Asthenia, neurocirculatory, cardiac neurosis and, *March*, 451, 453  
 Asthma and hay fever, etiologic relationship and clinical importance, *July*, 1125  
     cardiac hypertension and, *July*, 1052  
     food allergy and, *Jan.*, 121, 125  
     pollen, *Jan.*, 137  
 Athyreotic cretinism, *May*, 843  
 Auricular fibrillation, *July*, 1041  
     flutter, *July*, 1040  
 Avitaminosis, obesity and, differentiation, *Jan.*, 24
- BACK, low, disability of, diagnosis and treatment, *May*, 893  
 Bacterial endocarditis, subacute, *July*, 1011  
 Basedow's disease in children, *May*, 835  
 Belching, dyspepsia and, *May*, 648  
 Bemax, *July*, 1237  
 Beriberi from vitamin B<sub>1</sub> deficiency, *May*, 742  
 Betabion, *July*, 1238  
 Betaxin, *July*, 1238  
 Blindness, night, from vitamin A deficiency, *May*, 739  
 Blood pressure, normal, *Jan.*, 220  
     tissue culture of, in leukemia in childhood, *Jan.*, 115  
     transfusion in pneumonia in children, *Jan.*, 203  
 Bone, rider's, *Jan.*, 269  
 Brain in essential hypertension, *Jan.*, 225  
 Broadbent's sign, *July*, 975  
 Bronchocele in children, *May*, 832  
 Bronze diabetes, *May*, 863  
 Buerger's disease, *Jan.*, 245  
 Burns, x-ray, ulcers of leg from, *Jan.*, 253
- CACHEXIA strumipriva, *May*, 847  
 Calcinosis, *May*, 868  
 Carbohydrates in pregnancy, *March*, 550  
 Cardiac diagnosis, missed, *July*, 1003  
     insufficiency, early recognition, in presence of pregnancy, *July*, 1059  
     neurosis, arrhythmias and, *March*, 454  
     coronary thrombosis and, *March*, 459  
     heart murmurs and, *March*, 462  
     hypertension and, *March*, 458  
     misinterpretation of symptoms and signs, *March*, 461
- Cardiac neurosis, neurocirculatory asthenia and, *March*, 451, 453  
     organic heart disease and, *March*, 457  
     paroxysmal tachycardia and, *March*, 456  
     recognition, *March*, 449  
     rheumatic valvular heart disease and, *March*, 457  
     treatment, *March*, 440  
     pain, drugs in, *July*, 1080  
     psychoneuroses, *March*, 450  
     rates and rhythms, abnormal, diagnosis and treatment, *July*, 1033  
     rhythms and rates, drugs in, *July*, 1081  
 Cardiovascular diseases, diagnosis of, simplicity in, *July*, 959  
     drugs in, *July*, 1073  
     syphilitic, serologic tests in, *July*, 1021  
     treatment of, *July*, 1023  
     phenomena of vitamin B deficiency, *July*, 1231  
     system, changes in, from vitamin B<sub>1</sub> deficiency, *May*, 743  
 Cardiovascular-renal disease, *Jan.*, 219  
 Caries, dental, from vitamin C deficiency, *May*, 746  
     from vitamin D deficiency, *May*, 750  
 Cathartics in chronic myocardial failure, *July*, 1079  
 Celiac disease, *Jan.*, 149  
 Central nervous lesion, obesity and, *Jan.*, 29  
 Chemical nephrosis, acute, treatment, *May*, 778  
 Chest pain noncardiac cause, *March*, 461  
 Child, nervous, practitioner's responsibility toward, *March*, 525  
 Children, undernutrition in, *July*, 1167  
 Chlorosis, *March*, 389  
 Cholecystic disease, dyspepsia and, *May*, 658  
 Circulation, failure of, congestive and noncongestive, clinical features, *March*, 481  
 Colitis, spastic, *May*, 72  
     treatment, *May*, 731  
     ulcerative, treatment, *May*, 715  
 Collapse, *March*, 489  
     causes, *March*, 494  
     combined occurrence of congestive heart failure with, *March*, 498  
     treatment, *March*, 499 508  
 Collloid goiter, diffuse, in children, *May*, 832  
 Colon, diseases of, dyspepsia and, *May*, 662

- Colon, functional disorders, *May*, 721  
 allergy to food and, *May*, 728  
 environment and, *May*, 726  
 etiology, *May*, 724  
 fear of disease and, *May*, 727  
 heredity and, *May*, 729  
 irregular habits and, *May*, 729  
 laxatives and, *May*, 728  
 physical signs, *May*, 721  
 symptoms, *May*, 721  
 treatment, *May*, 731
- irritable, *July*, 1107  
 case histories, *July*, 1116-1124  
 diagnosis of, *July*, 1109  
 etiology of, *July*, 1108  
 treatment of, *July*, 1113
- Colonic neuroses, *July*, 1107
- Coma, diabetic, prevention of, *Jan.*, 11
- Congenital goiter, *May*, 831  
 hemolytic anemia in infancy and childhood, *March*, 401  
 hypertrophy of thyroid gland, *May*, 831  
 myxedema, *May*, 847
- Congestive myocardial failure, cathartics in, *July*, 1079  
 digitalis in, *July*, 1073  
 diuretics in, *July*, 1077  
 morphine in, *July*, 1079  
 salts in, *July*, 1079
- Conjunctival test for pollinosis, *Jan.*, 132
- Consciousness, temporary loss, heart disease and, *July*, 1010
- Constipation, *May*, 691  
 diagnosis, *May*, 696  
 dyspepsia and, *May*, 664  
 in disease, treatment, *May*, 705  
 symptoms, *May*, 694  
 treatment, *May*, 697
- Convulsions, heart disease and, *July*, 1010
- Coronary occlusion, acute, diagnosis of, *July*, 991  
 treatment of, *July*, 997  
 hypertension and, *July*, 1055  
 thrombosis, cardiac neurosis and, *March*, 459
- Corrigan pulse, *July*, 974
- Cowgill formula, *July*, 1232
- Cretinism, *May*, 843  
 athyreotic, *May*, 843
- Cryptorchism, gonadotropic treatment, *Jan.*, 207, 212, 213
- Cutaneous lesions from vitamin A deficiency, *May*, 739  
 manifestations of systemic disease, *May*, 861  
 test for pollinosis, *Jan.*, 129
- DEFENSIVE neuroses, recognition and management, *Jan.*, 271
- Deficiency diseases, dyspepsia and, *May*, 670  
 treatment, *May*, 719
- Dental caries from vitamin C deficiency, *May*, 746  
 from vitamin D deficiency, *May*, 750
- Dermatitis, food allergy and, *Jan.*, 126
- Dermatology, commonly missed diagnoses in, *March*, 621
- Dermatomyositis, *Jan.*, 267
- Diabetes, acid intoxication in, management, *Jan.*, 16  
 bronze, *May*, 863  
 early stages, care in, *Jan.*, 15  
 emergency program in, *Jan.*, 15  
 ferric chloride test in, *Jan.*, 14  
 precomatose case, first period management, *Jan.*, 18  
 protamine insulin in, *March*, 417  
 renal threshold in, *March*, 431  
 trauma in relation to, *March*, 441  
 treatment, in presence of high threshold, *March*, 432  
 of low renal threshold, *March*, 436
- Diabetic coma, prevention, *Jan.*, 11
- Diagnosis, pediatric, common errors in, *March*, 535
- Diarrhea, examination of stools and rectal discharges, *May*, 711  
 physical examination in, *May*, 710  
 proctoscopic examination, *May*, 712  
 roentgenologic examination, *May*, 713  
 symptoms, *May*, 709  
 treatment, *May*, 707
- Diathermy treatment of chronic gonorrhea in women, *July*, 1226
- Diathesis, hemorrhagic, from vitamin C deficiency, *May*, 746
- Diet, daily, during pregnancy and lactation, *March*, 560  
 during pregnancy and nursing period, *March*, 547  
 in chronic arthritis, *March*, 520  
 in heart disease, *July*, 1085  
 in obesity, directions for, *Jan.*, 31-37
- Digitalis, Eggleston method of administration, *May*, 766  
 in congestive myocardial failure, *July*, 1073  
 rational use, *May*, 761  
 toxic effects, *May*, 763
- Dinitrophenol in obesity, *Jan.*, 38
- Disability, low back, diagnosis and treatment, *May*, 893

## SYMPOSIUM ON DISEASES OF CHILDREN

The following clinics are included in this Symposium:

C. Loring Joslin: SOME CAUSES OF MALNUTRITION IN INFANCY.

William S. Love, Jr.: THE DIAGNOSIS OF HEART DISEASE IN CHILDREN.

James G. Arnold, Jr.: THE DIAGNOSIS AND TREATMENT OF OTITIC MENINGITIS.

Edward A. Looper: INFECTION OF THE NASAL ACCESSORY SINUSES IN CHILDREN.

H. Whitman Newell: THE EFFECT OF HEAD INJURY ON THE BEHAVIOR AND PERSONALITY OF CHILDREN: A STUDY OF 20 CASES.

Cyrus F. Horine and George S. Baker: ACUTE EMPYEMA IN CHILDREN: DURATION OF ILLNESS PRIOR TO TREATMENT A FACTOR IN MORTALITY RATE.

J. Edmund Bradley: DIAGNOSIS OF THE CAUSES OF LOW-GRADE ABDOMINAL PAIN IN CHILDREN.

T. Campbell Goodwin: THE TREATMENT OF ACUTE NEPHRITIS AND ITS COMPLICATIONS IN CHILDHOOD.

Leon Freedom: PROGRESSIVE BIRTH PALSIES.

Harry M. Robinson: TREATMENT OF SYPHILIS IN INFANTS.

## CLINIC OF DR. C. LORING JOSLIN

FROM THE DEPARTMENT OF PEDIATRICS, UNIVERSITY OF  
MARYLAND MEDICAL SCHOOL

### SOME CAUSES OF MALNUTRITION IN INFANCY

THIS presentation will offer some concepts concerning the possible causes of an infant failing to make a progressive or normal gain in weight during the first year of life. Cases illustrating the more frequent causes of malnutrition in infancy with results of treatment will be presented. No attempt will be made to discuss malnutrition in the preschool or older child.

Malnutrition is all too common in pediatric practice. In the dispensary patient, it is frequently a result of the present economic distress because the parents have been unable to purchase sufficient food for normal growth and health. In private practice, the undernourished child frequently presents himself, not as an economic problem, but as a diagnostic and therapeutic difficulty. Malnutrition in the private patient who has freedom from economic stress may be due to one of many causes, or to a combination of several. The etiology is not always clear and may require rather lengthy clinical and laboratory studies before it is apparent. The average medical student does not see as many cases of extreme malnutrition (marasmus) today as were seen twenty years ago. This is due to simplified methods of infant feeding and a better knowledge of underlying conditions. The student is likewise taught that the growth and development of the infant are his direct responsibilities. He soon recognizes that the baby ordinarily will gain if the mother follows the physician's directions and if the child does not present any congenital abnormality. If the baby does not gain on an adequate diet, then there is an error in judgment as regards the particular infant in question. Uncomplicated malnutrition is regrettable be-

cause it is a preventable disorder easily controlled by modifying the diet to suit the digestive characteristics of the individual infant. When other factors enter into the picture, an under-nourished infant may well represent a difficult problem.

A good general outline of the causes of malnutrition is a modification of one offered by Wright, as follows:

#### FAILURE TO GAIN WEIGHT

I. Constitutional or organic	{	Congenital	{ Anatomical, <i>e. g.</i> , amyotonia congenita. Congenital heart disease. Defective cerebral development. Various other congenital anomalies.
		Acquired	{ Intracranial hemorrhage. Physiological, <i>e. g.</i> , endocrine disorders.
II. Infection. . . .	{	Parenteral	{ <i>e. g.</i> , otitis media, mastoiditis, pyelitis, tuberculosis, syphilis.
		Enteral	{ <i>e. g.</i> , diarrheal diseases.
III. Food. . . . .	{	Quantity	{ Insufficient calories or too many calories.
		Quality	{ Incorrect formula—fat, protein, carbohydrate, salts, iron, vitamins, etc.
IV. Environment.	{	Home.	
		Outside.	

**Congenital Anomalies.**—*Amyotonia congenita* is among the organic causes of congenital origin. It is rare, but, when it does occur, demands accurate diagnosis because upon this depends prognosis. The disease is thought by some to be a muscular dystrophy, of the Werdnig-Hoffmann type, while others call attention to transitional forms, which possibly connect it with spinal muscular atrophy. The exact etiology is unknown. The chief symptoms concern the muscles, those of the lower extremities being so weak the infant is unable to move its legs. The upper extremities are usually moved, but feebly so; the intercostal muscles are usually involved, while the diaphragm and muscles supplied by the cranial nerves escape. The reflexes are diminished or absent. Various degrees of amyotonia occur, depending on the stage at which the disease is first seen. It either remains stationary or progresses very slowly and the child usually dies of intercurrent infection. Treatment is of no avail. The following case illustrates this condition:

6/14/28. (A.W.)	Age: four months.
Complaint:	Failure to grow and develop.
Family History:	One child living and well. One infant was recorded to have died as a result of "wasting disease" at six weeks of age.
Past History:	Natural birth. Birth weight: 7 pounds.
Present Illness:	Weak and feeble since birth. Weak cry. Has not gained since birth. Stools normal. No vomiting. Feedings: breast-fed for several weeks. Has also been fed modified cow's milk and condensed milk.
Physical Examination:	Lack of development of muscles of entire body, especially of lower extremities (flaccid paralysis). Muscles soft, flabby and general atonic condition. Knee jerks present. No impairment of sensation. Feeble respiratory movements.
Diagnosis:	Amyotonia congenita.

*Congenital heart disease*, in which there is cyanosis, with clubbing of the fingers and toes, is likely to be accompanied by a general malnutrition. The physical examination along with these symptoms should enable the physician to make the diagnosis and to account for the malnutrition on this basis. It is well to remember that frequently congenital anomalies are multiple and others should be searched for.

*Congenital cerebral developmental defects* are also among the causative factors of malnutrition in infancy. These children may apparently do well for a while and then cease to develop normally. In other cases the infant is retarded from the beginning. The disorders may be classified as congenital cerebral diplegias, paraplegias, or hemiplegias. They result in the birth palsies, of which the spastic diplegias are most common. These children rarely are able to stand, walk or talk; their extremities are held spastic and the lower extremities are usually crossed. They are mentally retarded and show little signs of intelligence. As feeding problems they are discouraging since they take little interest in food, especially solid food, so that feedings must be forced upon them. The prognosis at best is poor in these cases and they usually succumb to intercurrent infections. Clinically they are likely to be confused with the picture of intracranial hemorrhage. The differential diagnosis depends largely upon an examination of the spinal fluid, which shows evidence of either fresh bleeding or old bleeding, in the event of hemorrhage, and the absence

of blood and its products in the palsies. In the later months, the tape measure may give evidence of cerebral disorder and occasionally a microcephalic is diagnosed by this simple method. It is important to diagnose the condition, because it is our experience that the mothers of these children are frequently unaware of the nature of the disorder and go from physician to physician in an attempt to rear a normal child, without realizing that their child will never be normal.

**Acquired Defects.**—*Intracranial hemorrhage* has not only recently been recognized as the most frequent cause of death in the newly born, but it may be the cause of an infant failing to gain normally. One of the more common symptoms in the less severe cases of intracranial hemorrhage, is failure to nurse properly and to make a satisfactory weight gain. Fortunately, when there is only moderate intracranial bleeding at birth, the condition clears up spontaneously and the infant will make a normal gain. Frequently, though, this is not the case and it is later observed that the infant is underweight and is not developing normally. Vomiting may result from increased intracranial pressure as a result of intracranial hemorrhage at birth and thus interfere with the nutrition of the child. Vomiting is not a common nor a characteristic symptom of intracranial hemorrhage, but occasionally occurs. The symptoms one is usually able to elicit, suggesting intracranial hemorrhage as a cause of failure to progress normally, are rigidity of neck muscles (intermittent), adductor spasm of lower extremities, spasticity of upper and lower extremities, and attacks of cyanosis.

The following case illustrates the influence intracranial hemorrhage may have upon the weight gain of an infant.

2/18/34. (L.J.N.) Age: two months.

Complaint:	Not gaining. Vomiting
Family History:	Negative.
Past History:	Low forceps delivery. Birth weight, 8 pounds 8 ounces. Formula: modified cow's milk.
Present Illness:	Has not gained since birth. Vomiting since four weeks of age. Change of formulas has no effect upon weight gain or vomiting
Physical Examination	Slight rigidity of neck and spasticity of extremities, especially marked if infant is excited or cries. Adductor spasm of lower extremities. Marked malnutrition

Diagnosis: Intracranial hemorrhage at birth. Vomiting and malnutrition, secondary to increased intracranial pressure, resulting from hemorrhage.

Treatment: Lumbar punctures.

Figure 69 shows graphically the weight gain of this infant before and after institution of treatment.

**Endocrines.**—The endocrines play an important part in the growth and development of the infant. In most cases, an endocrine imbalance is clinically manifested by a faulty growth.

Fig. 69.

*Note.*—Infant gained immediately after first lumbar puncture, which was repeated until pressure symptoms disappeared.

Perhaps the most classical example of this is seen in the cretin, who represents an infant with a deficient secretion or absence of thyroid hormone. These children are short, have coarse features, dry skin, broad nose, frequently a protruding tongue, and show a general lack of development both mentally and physically. The important differential diagnosis is between the cretin and the mongolian idiot. In clear-cut cases there is little difficulty encountered, whereas in others a very careful examination may be necessary. The roentgenographic studies

of the centers of ossification along with growth age and mental age are of great value in orienting oneself as to the status of the child. It is important to remember that large doses of thyroid extract are sometimes necessary to achieve the best results, doses which may bring about a state of temporary hyperthyroidism.

The pituitary is intimately connected with the various types of dwarfs. Disorders of the pineal gland and the thymus gland are not clear as yet. A diagnostic difficulty is frequently encountered where there is a pluriglandular dysfunction.

**Parenteral Infections.**—These are frequent causes of an infant not making the normal gain in weight. Some children are much more susceptible to recurring infections than others, and with each recurring infection the child is retarded in its nutritional gain, until a very definite state of malnutrition exists. *Otitis media* is one of the most frequent of the parenteral infections interfering with nutrition, not infrequently causing a diarrhea with weight loss. *Mastoiditis*, secondary to otitis media, sometimes interferes with nutrition. It is not the usual mastoiditis to which I wish to call attention, but the so-called "hidden mastoiditis," in which there may be no local symptoms, such as swelling or tenderness over the mastoid. Otoscopic examination of the ear likewise does not reveal any appreciable involvement of the tympanic membrane, the diagnosis being based upon the clinical picture as a whole. These cases fortunately are not frequent, but do occur. The onset is usually sudden, with a diarrhea, which persists in spite of all forms of treatment. The infant becomes rapidly dehydrated, toxic, loses weight until it is merely skin and bones. Death always follows unless the correct diagnosis is made and the mastoid is opened and drained. The condition is illustrated by the following case:

10/20 31. (C.T.) Age: five months.

Complaint: Diarrhea, loss of weight.

Family History: Negative.

Past History: Negative. Developed normally until four months of age.

Present Illness: At four months infant developed diarrhea, which has persisted until the present. During the past three weeks the infant has been treated in the hospital and

the diarrhea has become progressively worse in spite of all treatment, averaging from 10 to 15 stools per day. There was a weight loss of several pounds before entering hospital and this loss of weight has continued.

Physical Examination: Extreme malnutrition, dehydration and toxicity. No local evidence of mastoid involvement. Tympanic membrane of right ear shows slight congestion around the circumference; the drum is otherwise negative. Stool cultures, blood, etc., negative.

Diagnosis: Mastoiditis. Diarrhea and malnutrition secondary to a hidden mastoid infection.

Figure 70 shows weight record of this case while in the hospital.

*Pyelitis* is another cause of malnutrition, especially in the female infant, although it may occur in the male as well. These infants are handicapped in their development, they are frequently anemic in appearance and fail to gain because of an active infection in the kidney. Recognition of the cause of the failure to gain depends on completeness of urinary studies. Frequently the diagnosis is missed because only one urinary specimen has been examined, and that at a time when the patient is not eliminating pus in the urine. Anomalies of the genito-urinary tract are often a source of chronic infection and result in malnutrition. These may be so well masked that only necropsy discloses them, as for example in the case of aberrant ureter with infection.

*Tuberculosis* as such is not a common cause of malnutrition in infancy. Here diagnosis does not depend upon physical examination alone, but on tuberculin tests and x-ray findings. The diagnosis should be made when the infant is still well nourished, rather than later, when a state of malnutrition exists, if treatment is going to be effective.

*Syphilis* is another cause of faulty development and failure to grow properly. These cases are pathetic when the condition is marked at birth. The picture is a familiar one and I should only like to call attention to the importance of treating the mother during pregnancy, thus giving prophylactic treatment rather than curative. Attention is also called to the fact that a negative Wassermann during the first few months of life does not rule out congenital lues.

**Enteral Infections.**—The *diarrheal diseases*, while still a problem during the summer months, are not the frequent causes

Fig. 70.

*Note.*—There was a loss in weight of 2 pounds after admission to the hospital, which occurred before the mastoid was drained. Following the mastoidectomy the diarrhea immediately ceased, the weight loss was checked, the infant gained slowly for a time and then made an uninterrupted progress to normal weight and health.

of extreme malnutrition as in the past. During the past two years we have been able to carry seventy-five per cent of

our cases of diarrhea and dysentery through their illness without any loss in weight, and when the average of all cases has been taken, there has been a slight gain in weight during the attack of diarrhea. This is quite a contrast to the loss of weight we formerly saw. Many infants fail to make their normal gain in weight during infancy because of recurring attacks of diarrhea. These repeated attacks may be due to intolerance to some one ingredient of the diet, such as too much fat, or carbohydrate, or to too large a quantity per feeding. Recurring parenteral infections may produce the same clinical picture. Of the enteral infections dysentery is the most common, and not infrequently occurs unrecognized, because of the absence of macroscopic blood in the stools.

In the prevention of weight loss from diarrheal diseases, the addition to the diet of the fully ripe banana, or the dehydrated banana powder has proved most effective.

*Typhoid fever* likewise is no longer the producer of such a state of extreme malnutrition as we used to see because of improved methods of feeding these cases.

**Quantity of Food.**—The quantity of food fed to an infant has an obvious effect on his general state of well-being. If he is not getting sufficient calories to supply his maintenance requirements along with his growth requirements, he will not gain. Likewise many infants will not gain if given too much food. There has been a strong tendency during recent years to allow the child to decide for himself the question of how much food he should have. This may be a satisfactory method for some infants, but for others it is not a safe guide. Many an infant who is getting too much food, having colic, and crying frequently will take eagerly an increase in the formula, when what the infant needs is less food. According to my experience, the greatest difficulty the physician has today is in estimating the total caloric requirement of the individual infant. Before the introduction of simplified infant feeding (whole milk modifications) one would see many infants failing to gain because of the quality of the food—but now this has changed, and many infants are seen failing to make an optimum gain because the total caloric intake is not properly adjusted to the individual infant. Those infants failing to gain because of too much food may have recurring attacks of

diarrhea and vomiting, or the infant may be simply refusing part of its feedings. It is well to remember, that there is a maximal point at which an infant will gain, a minimal point, and an optimal point. Many infants are seen suffering from a moderate degree of malnutrition, because such infants are having to subsist on the maximal or minimal number of calories and are not receiving the optimal number upon which they would gain best.

The following case will illustrate the importance of the total caloric intake in relation to the infant's weight gain.

Fig. 71.

*Note.*—In the above chart it will be seen that the infant, although given various formulas and different types of food, made little gain in weight for six months. When the total caloric intake was adjusted to meet the requirements of the infant, there was an immediate and continued weight gain.

11/21/30. (L.H.B.) Age: six months.

Complaint: Not gaining.

Family History: Negative.

Past History: Birth weight, 7 pounds 12 ounces Feeding: breast two months, modified cow's milk, goat's milk, pre-digested milk, condensed milk, cow's milk.

Present Illness: Has gained only 1½ pounds in six months. Vomiting at irregular intervals. Constipated. Present formula: milk, 15 ounces; water, 15 ounces; sugar, 2 table-spoonfuls (42 calories per pound)

Physical Examination: Negative, except for marked degree of undernutrition

Diagnosis: Malnutrition, extreme Feeding, regulation of

Treatment: Formula adjusted to caloric requirements of infant. Milk increased to 18 ounces, sugar to 3 tablespoonfuls (57 calories per pound). No other change was made in the care and feeding of the infant. Formula later increased as baby gained.

**Quality of Food.**—Some infants may receive an adequate quantity of food for proper gain in weight, but have difficulty in gaining because the quality is not suitable.

Premature babies present a special problem, inasmuch as such infants are born with sufficient reserves of iron and other accessory factors to take care of only the immediate needs. The rate of growth is relatively rapid and the premature infant quickly outstrips his reserves so that he is in danger of being undernourished unless the need for the accessories is met. The normal infant tends to grow at a rate commensurate with his natal reserves until the second month is reached. At this time growth has progressed to a point where the stores are not sufficient, and the child has what has been termed a physiologic anemia. Usually the child makes a physiologic adjustment to the situation, and after a variable period, depending on the individual, resumes normal growth.

There are many factors entering into the maintenance of normal nutrition, and it would appear that our concept of normal nutrition is changing. Certainly it is clear that improved nutrition may be obtained for many infants and children, who are generally considered to be in a normal state of health, by the addition of certain vitamins and minerals to their regular diet.

Various degrees of undernutrition, especially nutritional anemias, are produced by a deficiency in the diet, or a lack of balance of certain minerals, such as iron, calcium, phosphorus, and perhaps copper. It has been shown that a preponderance of one mineral may interfere with the utilization of another. From the biochemical standpoint, there are such problems as the secretions of the various ferments that aid in digestion. For example, the amount of hydrochloric acid secreted in the stomach may have an important part in the mechanism of digestion and nutrition.

Our knowledge concerning the vitamins has been greatly increased during recent years, yet our information is still in-

complete. The clinical picture produced by a deficiency of vitamins C and D in the diet is a familiar one to all. The picture of an inadequate amount of vitamins A, B and G is not so clear, yet they are necessary vitamins, and perhaps more important than we have thought. This is shown graph-

Fig. 72.—Effect of vitamin B complex upon growth of rats.

*Note.*—Vitamin B-free diet was fed for six weeks to 2 rats. Rat 4 died; rat 5 shows progressive loss of weight until vitamin B was added to the diet at six weeks, then follows a progressive gain in weight. It will be seen that without the vitamin B complex in the diet, the rats lose appetite and weight, and soon die. When the vitamin B complex is added to the diet, normal nutrition is rapidly regained, as shown by this chart.

ically in Fig. 72, in which there is given the weight curve of two rats on a vitamin B-free diet for a period of six weeks, after which time the vitamin B complex is added to the diet in the form of a special cereal mixture.

It is also interesting to note that improved nutrition may be obtained by including additional vitamin B and perhaps

minerals in the regular diet of many infants. This is shown in Fig. 73, where a cereal<sup>1</sup> mixture rich in vitamin B and minerals was substituted for the regular cereal being given a group of infants in an orphanage, no other change being made in the diet or routine care. The group receiving the cereal, enriched with vitamins and minerals, had an increased rate of gain in weight and growth as compared to the control group.

The individual tolerance of fat, protein, and carbohydrate should be considered in the feeding of infants who are not making normal progress. Carbohydrate intolerance is not frequent, and protein intolerance causes little trouble, except from an allergic standpoint, as in eczema. If this condition develops early in life the infant's nutrition and growth are temporarily interfered with. Fat intolerance is quite frequent;

*Effect of Special Cereal on Growth of 20 Infants*

	<i>Height in inches</i>			<i>Weight in pounds</i>		
	<i>Initial</i>	<i>After 2 mos.</i>	<i>Gain in inches</i>	<i>Initial</i>	<i>After 2 mos.</i>	<i>Gain in pounds</i>
<i>Control Group</i>	32.1/4	33 1/4	1.0	26.1	27.6	1.5
<i>Special Cereal</i>	30	31.5	1.5	22.13	24.14	2.0

*Special Cereal rich in Vitamin B and minerals*

Fig. 73.

it may be recognized by vomiting, crying from colic, frequent stools, or constipation. The effect of fat intolerance upon nutrition is shown by the following case:

1/12/34. (R.D.G.) Age: five weeks.  
 Complaint: Crying. Not gaining.  
 Family History: Negative.  
 Past History: Natural birth; birth weight, 9 pounds 9 ounces.  
 Present Illness: Crying and has not gained since birth.  
 Physical Examination: Negative, stools frequent and contain large number of fat curds.  
 Diagnosis: Colic. Fat intolerance.  
 Treatment: Fat-free milk.

The bacteriologic flora of the intestinal tract has recently received considerable attention and may at times have a re-

<sup>1</sup> Cerevim.

tarding effect upon nutrition. These cases are frequently diagnosed as chronic intestinal indigestion, and there may be a relationship with celiac disease. The part that the intestinal flora plays in some conditions is not as yet entirely clear, and needs further study.

**Environment.**—The surroundings in which the baby is placed frequently have an important bearing upon its nutrition and general health. The nervous mother, for example,

Fig. 74.

*Note.*—There was a gain in weight as soon as fat-free milk was given infant, crying also immediately ceased.

usually leaves her mark upon the baby so that the infant is overexcitable, unable to relax, and generally underweight. Needless to say, the environment outside of the home, as well as within, has an important bearing on the health of the child. Pure fresh air is a prime requisite in the life of every infant. When an infant is deprived of an adequate amount of sunshine its nutrition suffers. During the winter months it is frequently advantageous to compensate for this lack by exposure to the ultraviolet light. It is important that a pains-

taking investigation be made into the environmental factors in every case of failure to gain weight during infancy.

**Summary.**—Little emphasis has been placed upon the treatment of undernutrition in infancy, but an attempt has been made to stress the importance of making a diagnosis as to the cause of the undernutrition. Without a correct diagnosis the treatment may not only be difficult, but may prove costly because the fundamental cause is untouched. Malnutrition in infancy (except in cases of congenital abnormalities) is a preventable condition and should be treated from a prophylactic, rather than from a curative standpoint.

## CLINIC OF DR. WILLIAM S. LOVE, JR.

UNIVERSITY OF MARYLAND

---

### THE DIAGNOSIS OF HEART DISEASE IN CHILDREN

IN considering this title it becomes obvious that no adequate discussion of all of its phases could be encompassed in a paper of this scope. I shall therefore limit myself to those conditions in which difficulties of diagnosis most commonly exist, and which are fairly frequent in occurrence.

#### CONGENITAL HEART DISEASE

Maude E. Abbott has rendered a great service by giving us a clinical classification of congenital heart disease which is simple and descriptively to the point. This classification is based upon the presence or absence of cyanosis. While cyanosis may be met with in many conditions, severe cyanosis recurring or constantly present in children is almost always due to congenital heart disease, unless other cause be more or less obvious. The cyanosis of congenital disease of the heart is due to a shunt from the venous to the arterial circuit. It is important to emphasize that the direction of the shunt must be venous-arterial, for only if the shunt is in this direction will the amount of reduced hemoglobin in the arterial blood be sufficient to cause cyanosis. Arteriovenous shunts do not lead to cyanosis unless eventually the direction of flow be reversed by heart failure or other complicating factors; then cyanosis occurs.

We may clinically divide congenital heart lesions into:

1. Those in which no shunt is present—the acyanotic group.
2. Those in which an arteriovenous shunt exists—the potentially cyanotic group.

3. Those in which the shunt is venous-arterial—the cyanotic group.

The variety of lesions which may occur under any of these headings except the second is too great to permit of complete discussion. Only those encountered with some frequency, and permitting of clinical diagnosis, are here described.

#### THE ACYANOTIC GROUP

**Dextrocardia.**—Mirror image dextrocardia with complete situs inversus of the viscera produces no symptoms, and in no way handicaps the patient. The apex of the heart lies to

Fig. 75.—Teleoroentgenogram of heart, mirror image dextrocardia with situs inversus. Note absence of hypertrophy, gas bubble in stomach on right liver on left.

the right and other viscera are transposed. Figures 75 and 76 show the roentgenogram and electrocardiogram of such a case. The electrocardiograms obtained from such cases are typical and are explained in the legend of Fig. 76.

Dextrocardia with partial situs inversus or isolated dextrocardia is usually associated with complex cardiac defects defying complete clinical diagnosis and is usually to be placed in the cyanotic group. Figure 77 presents the x-ray of such a case, a cyanotic infant showing at autopsy isolated dextrocardia, transposition of the aorta and pulmonic artery, a large defect of the interventricular septum, and pulmonic stenosis.

**Coarctation of the Aorta.**—This condition may occur as

Fig. 76.—Electrocardiogram from same patient shown in Fig. 75. All waves in Lead 1 are *negative*, Lead 2 records what would usually be Lead 3, and Lead 3 records what would be Lead 2. These findings occur because of the altered position of the heart in relation to the leads. There is no axis deviation

a part of complex anomalies, and does not usually permit of diagnosis under these circumstances. The type known as the adult form is more readily diagnosed but is usually overlooked until adolescent or adult age has been reached. Anatomically there occurs a constriction of the aorta varying from partial to complete, and usually at the site of its junction with the ductus arteriosus. Hypertension is commonly associated with this anomaly, and in all cases in which the blood pressure is

elevated without obvious cause, evidences of this lesion should be sought for. The blood pressure is elevated in the upper extremities, and diminished in the lower. There is often a perceptible lag in the femoral pulse when taken synchronously with the radial. Collateral circulation takes place principally through the intercostal, internal mammary and branches of the subclavian and carotid arteries. These vessels become

Fig. 77.—Isolated dextrocardia. Note marked cardiac enlargement, liver on right. From a case of morbus caeruleus showing at autopsy isolated dextrocardia, transposition of aorta and pulmonary artery, pulmonic stenosis, large interventricular septal defect. The electrocardiogram is similar to that shown in Fig. 76, but axis deviation is present.

enormously dilated and may be palpated as twisted cords. x-Ray reveals left ventricular hypertrophy, a prominent right border of the aorta, at times amounting to aneurysmal dilatation, and notching of the ribs caused by the dilated tortuous intercostal arteries. These cases are not infrequently encountered. I have seen 6 such, 5 in adults in which 2 were verified at autopsy, and 1 discovered on the dissecting table. In this last case there was also a stenosis of the right sub-

clavian artery. One case was that of a girl of thirteen who was referred because of an unexplained hypertension (Fig. 78).

**Valvular Lesions.**—Bicuspid semilunar valves are not infrequent, as are anomalies of other valves. They usually cannot be diagnosed as such clinically although incompetency may be present. Mitral, tricuspid, pulmonic and aortic stenosis and insufficiencies may occur. Fenestrations of valves are rather common. This defect does not permit of clinical diagnosis and

Fig. 78.—Coarctation of aorta. Orthodiagram of child thirteen years old. Note full-sized heart, absence of aortic knob and prominence of aorta to right. Notching of ribs is distinct. Collaterals were palpable in interscapular region on left.

its significance is uncertain. Lewis and Grant have pointed out the frequency with which bicuspid aortic valves become the seat of subacute bacterial endocarditis.

#### THE POTENTIALLY CYANOTIC GROUP

In these instances of arteriovenous shunt are found some of the commonly seen congenital defects such as persistent ductus arteriosus, patent foramen ovale, and defects of the interauricular or interventricular septa. It is a common mis-

take to think that the fetal passages close promptly at birth. Patten has shown that functional closure of the foramen ovale is represented by a sharply rising curve during the first six weeks of life which reaches a maximum at about three months. Complete anatomical closure may not take place in about 25 per cent of all individuals. Scammon and Norris report that obliteration of the ductus arteriosus reached its maximum at the end of three months, and that it had taken place in over

Fig. 79.—Interauricular insufficiency (septal defect). Note contour of heart and auricular enlargement. No symptoms or signs except murmur. Electrocardiogram is normal.

95 per cent of the cases examined by the end of the first year. Since the shunt in these cases is arteriovenous, cyanosis of the newborn could not be attributed to either of these lesions acting alone, and moreover the foramen and ductus are normally patent at birth. Patients in this group may usually be expected to reach adult life, and many middle age, without untoward symptoms. Cyanosis may occur transiently as a result of temporarily increased pulmonic pressure or terminally with heart failure. In any of the conditions enumerated bacterial

endocarditis, usually of the subacute type, may occur as a complicating factor.

**Interauricular Septal Defects Including Patent Foramen Ovale.**—These patients are often of delicate build, with delayed puberty. There is usually an early systolic or late diastolic murmur near the sternum in the third or fourth interspace. By x-ray examination the aorta is found to be

Fig. 80.—Interventricular insufficiency (septal defect). Note shape of heart and hypoplastic aorta. Electrocardiogram reveals intraventricular conduction defect. In attacks of precordial pain marked dilation of the pulmonary conus could be observed.

hypoplastic and the auricles dilated, giving a characteristic appearance to the contour of the heart (Fig. 79). The electrocardiogram shows no significant deviations from normal.

**Interventricular Septal Defects.**—*Maladie de Roger.*—The commonest site for this lesion is just below the aortic valves. I have seen 2 such cases, one in a woman of forty-eight dying of carcinoma of the ovary, with metastasis to the lungs, and one in a young girl of eighteen. The older woman

at autopsy had an interventricular opening measuring 3 mm. There had been no symptoms during life. There was present a loud harsh systolic murmur in the fourth interspace maximal about 2 cm. from the sternum. No thrill was detected, but this is not uncommonly present. The second patient has always been somewhat delicate, fatigues readily, and has occasional severe attacks of precordial pain during which the pul-

Fig. 81.—Persistent ductus arteriosus. Note prominent conus. Fluoroscopically there was marked pulsation of the conus. The typical murmur of this condition was present. There were no symptoms. The electrocardiogram is normal.

monic conus may be observed by fluoroscopic examination to be markedly dilated. Figure 80 presents the *x*-ray of this patient, showing a globular heart and hypoplastic aorta. These patients not infrequently show aberrations of the QRS waves in the electrocardiogram and this patient presented such abnormalities. The patient was normally developed. There was a loud, rough systolic murmur with a thrill in the fourth interspace near the sternum. The pulmonic sounds were re

duplicated. Cyanosis has not as yet been noted, and indeed terminal and transient cyanosis is less common in patients with interventricular septal defects than in those having defects of the auricular septum.

**Persistent Ductus Arteriosus.**—I have seen 3 cases so diagnosed, all occurring in young males. No symptoms were present in any and cyanosis had never been present. One lad ran on his school track team. In 2 of these cases the typical "machinery murmur" beginning just after the first sound, reaccentuated with the second sound and dying away in early diastole was heard maximally in the second interspace in the pulmonic valvular area. In the third case the murmur was systolic and heard in the third interspace. The pulmonic second sound was accentuated in all, due to increased pulmonic pressure resulting from the aortic-pulmonary artery shunt. Cardiac enlargement was not present in any of these cases, but it may occur. The x-ray is of great help in confirming the diagnosis, revealing a marked dilatation of the pulmonic conus, and fluoroscopically very active pulsation of this portion of the cardiac shadow may be observed. Figure 81 is the x-ray of one of the patients mentioned above. The electrocardiogram is not significant but is of help in distinguishing this lesion from pulmonic stenosis. In the latter lesion right axis deviation usually occurs.

#### THE CYANOTIC GROUP

The anomalies found in this group are often so complicated that certain diagnosis is impossible. True cases of morbus caeruleus always belong here. Such defects as total absence of the auricular, ventricular and aortic septa, or combinations of these, pulmonic stenosis and septal defects, atresia of valves with septal defects and transposition of the great vessels make up the bulk of lesions in this group. Cyanosis may be present at birth or occur subsequently. The majority of patients suffering with such lesions do not reach adult life and death often occurs a few days or months after birth. Pulmonic stenosis is the commonest defect and is usually associated with interauricular or interventricular septal defects. According to Abbott's statistics, the combination of lesions—pulmonic stenosis, defect of interventricular septum, dextroposition of

the aorta and right ventricular hypertrophy—known as the tetralogy of Fallot is the commonest of all lesions of the cyanotic group. I have seen a number of cases of congenital heart disease both clinically and at autopsy and have as yet to recognize the tetralogy. Whenever pulmonic stenosis is associated with a defect in the septum the raised pressure in the right heart leads to a venous-arterial shunt. Cyanosis becomes marked, and clubbing of the fingers is common.

Fig. 82.—Pulmonic stenosis with patent foramen ovale. Teleoroentgenogram from seven-month infant cyanotic since birth. The anterior aspect of heart is formed by the enormously dilated right auricle and hypertrophied right ventricle.

Polycythemia is often present. Dyspnea and syncopal attacks may occur.

In patients with pulmonic stenosis there is a rough systolic murmur, often accompanied by a thrill, present in the pulmonic valvular area. The pulmonic second sound is diminished. There is right heart enlargement and the pulmonic conus may become prominent. Other murmurs according to accompanying defects may be present. An infant seven months old had

been cyanotic from birth, becoming almost indigo in color during crying spells. There was cyanosis of the retina and a moderate degree of clubbing of the fingers and toes. The heart was enlarged (Fig. 82). In the third interspace there was a loud systolic murmur. There was no thrill. The pulmonic second sound was faint. Because of these signs it was reasoned that the child had a stenosis of the pulmonic valve

Fig. 83—Practical atresia of pulmonic valve. From same case as Fig. 82. The foramen ovale was widely patent.

of severe degree with a septal defect. It was thought that the systolic murmur heard was probably due to the septal defect rather than the stenosis. At autopsy there was found marked right ventricular hypertrophy, dilatation of the right auricle, stenosis almost amounting to atresia of the pulmonic valves, and a widely patent foramen ovale (Fig. 83). There is usually right axis deviation in the electrocardiograms of such patients. No tracing was obtained in the above case, but in 4 other

cases of pulmonic stenosis in which electrocardiograms were obtained such axis deviation was present in each.

In concluding the discussion of congenital heart disease, it is well to point out that except in cases with cyanosis there are no specific symptoms presented by these patients. Those with cyanosis sooner or later develop clubbing of the fingers and toes; dyspnea is commonly a symptom, and convulsions

Fig. 84.—Pulmonic stenosis without septal defect or shunt—typical contour of heart. This might be confused with a mitral heart, but examination in the right oblique position revealed no left auricular enlargement. Electrocardiogram showed right axis deviation. Cyanosis was not present but may occur in this condition because of increased deoxygenation in the capillaries.

and syncopal attacks not infrequently occur; polycythemia is often present. Congestive failure with its accompanying train of symptoms may develop in any congenital lesion causing myocardial embarrassment. Precordial pain may occur and is apt to be associated with dilatation of the pulmonic artery and conus. Congenital anomalies of other parts of the body are frequently to be noted and mongolian idiocy is rather com-

monly found in association with heart disease of the congenital type.

#### RHEUMATIC HEART DISEASE: THE SIGNIFICANCE OF THE APICAL SYSTOLIC MURMUR

The typical cases of rheumatic fever with joint symptoms or chorea need no discussion in this paper. However, in infancy and early childhood such typical cases are rarely seen. The rheumatic infections, including chorea and tonsillitis, are the most important causative agents in the production of heart disease in young people. It is therefore of importance to recognize atypical forms of this disease. In my experience, well over 25 per cent of adults with mitral stenosis give no history identifiable with that of rheumatic fever or chorea. The occurrence of vague aches or pains either in the muscles or joints of children should lead to a strong suspicion of rheumatic disease unless other explanation be afforded. In children who suffer from repeated attacks of tonsillitis the heart should be watched constantly. I recently saw a child of four stated to be normal by competent observers up to the age of three, but who had had frequent bouts of tonsillitis and who in the midst of such an attack became edematous. There was low-grade fever, dyspnea, generalized edema, and pleural effusion. An obvious mitral stenosis was present at this time. The child died twenty-four hours later. This child for the past year had suffered from nutritional disturbances, and nausea and vomiting had occurred often. Vomiting is frequently a symptom to be found in the rheumatic child, and may occur during periods of apparent good health. Doubtless this child had suffered from continuous low-grade rheumatic infection or at least frequent recurrences of such infection for some time.

Whenever a clearly defined valvular lesion is present in a child, it may be assumed that damage to the heart has occurred some time before its discovery, for such lesions do not manifest themselves during the course of an ordinary acute rheumatic infection. They become obvious when an infection has lasted some time, or has been recurrent.

Epistaxis is common in these children, and, while not diagnostic of itself, when occurring with other suggestive evidence,

points toward rheumatic infection. Abdominal pain may occur and if associated with nausea and vomiting may lead to the diagnosis of surgical abdomen. The occurrence of rheumatic nodules along the course of tendons and ligaments, and in the scalp is all too often overlooked, and when present they are invaluable in arriving at a correct diagnosis. They may persist long after active infection has apparently subsided. Skin rashes are at times present and may take the form of erythema multiforme.

Frequently the disease manifests itself only as an obscure malaise, with lassitude and unusual fatigability. There may be little or no fever. When the heart is involved there is almost always a tachycardia out of proportion to the severity of the illness or the height of the fever. Occasionally, however, I have seen bradycardias of sinus origin. Systolic murmurs are wont to occur over the precordium. I place less stress on these than on any other sign. It is true that they may be due either to actual valvulitis or to relaxation of a ring. However, they are so commonly present in febrile disease of any sort, in tachycardias, and in states of malnutrition that their presence cannot be emphasized as indicating actual cardiac damage. But when such a murmur appears during a suspected attack and lasts after the illness is apparently over, it is of more significance. If definite mitral stenosis or aortic lesions appear in long lasting illness, the diagnosis is certain. Dilatation of the heart out of proportion to the illness is strongly suggestive of cardiac involvement.

The occurrence of evidences of inflammation of the pleura and pericardium is of great importance. Pericarditis with a large effusion is not difficult to recognize. However, a friction rub may be the only evidence present, and the amount of fluid may be too small to recognize clinically. Pain over the precordium is not uncommon in pericarditis and indeed may occur in rheumatic carditis when pericardial involvement is not present. I recall a youth of fourteen who had had vague aches in his left shoulder, and had felt tired and run down for several weeks, who suddenly complained of precordial discomfort and breathlessness, and who on examination had a typical pericardial friction rub. He had a pulse of 120, and a temperature of 100° F. The heart sounds were clear. x-Ray

examination of the heart was negative. There was a moderate leukocytosis and the sedimentation rate was rapid. He was in bed four months with weakness, fatigability, tachycardia, and at one time a clear, straw-colored effusion into the right pleura. There was slight fever from time to time. When re-examined one year after recovery there was a definite mitral stenosis. Pleural effusion not infrequently occurs during the course of rheumatic infections.

Edema may at times be present. It has been my experience, as well as that of others, that edema occurring in rheumatic heart disease in children coming to autopsy is inevitably associated with an active infection of the heart, whether very definite clinical signs of activity have been present or not. Most frequently such edema is undoubtedly associated with heart failure. However, I have seen several cases in which it partook of the nature of nephrotic edema, being diffuse in character, and associated with considerable amounts of albumin in the urine, and a diminution of the serum protein. The case of a child of three coming to autopsy also had cholesterolemia. There was mitral stenosis, and an active valvular endocarditis of the rheumatic type. It should also be remembered that a constrictive pericarditis may lead to engorgement of the viscera and ascites. I have seen one such case in a child.

Laboratory findings are at times of considerable aid in the diagnosis of rheumatic heart disease. This type of infection is one of those most commonly associated with a rapid sedimentation rate of the erythrocytes and the sedimentation test should be done on all suspected cases. This test is unfortunately not diagnostic since an augmented rate occurs in many other conditions. However, when rapid in suspected cases, it gives further weight to the diagnosis. I have found it to be of more value in determining activity of infection in known rheumatic individuals. The rapid rate may persist long after other signs of infection have subsided. There is generally some degree of leukocytosis, and in protracted or severe cases definite anemia may occur.

In my experience the electrocardiogram gives invaluable aid in about one third of the cases. During periods of activity prolongation of the auriculoventricular conduction time is the most common abnormality noted. Abnormalities of the ST

segments and T waves also occur. Figure 85 is the electrocardiogram obtained from a colored child subject to recurring episodes of listlessness and slight fever, during such an illness. Four years previously there had been a typical attack of rheumatic fever, at the onset of which, however, the child already had mitral stenosis. Following that attack an aortic insufficiency developed. This electrocardiogram illustrates both prolongation of the auriculoventricular conduction time and aberrations in the ST segments. Changes in the ST segments

Fig. 85.—Active rheumatic carditis. Prolongation of auriculoventricular conduction time (PR interval 0.28 second). Note high take-off of ST segments in Lead 3.

and in the T waves may at times only be present in the precordial lead; therefore this lead should be routinely taken in suspected cases.

The x-ray offers little help in early cases. In those in whom large pericardial effusions have occurred, there is noted enlargement of the heart of a rather typical contour. If definite valvular lesions are present, the x-ray usually reveals changes in the contour of the heart and in its size, according to the lesions present.

**The Apical Systolic Murmur.**—The typical valvular lesions of rheumatic heart disease, mitral stenosis with or without aortic insufficiency and stenosis, offer little difficulty of diagnosis and will not be discussed further. Evaluation of the significance of systolic murmurs heard at the apex, transmitted or not transmitted, offers one of the most troublesome problems of cardiac diagnosis. It must be remembered that such murmurs are not uncommonly transient, and may occur in normal children as a result of exercise, excitement, or tachycardia due to any cause. They may be present in anemia, malnutrition or fever. They may occur rather obviously only during some phase of respiration; or when the patient is only in one position. Under these circumstances, and when associated with no other evidence of heart disease, I am inclined to attach no cardiac diagnostic significance to them. When they are persistently present, especially in a child who has had rheumatic fever, or in whom there is good reason to suspect rheumatic infection, I think they cannot be lightly dismissed. We have already seen that the murmurs of certain congenital lesions may be heard near this area. In many cases of mitral stenosis the diastolic or presystolic murmur is heard with difficulty or not at all, an apical systolic murmur alone being present. The diastolic murmur may be heard only in a very limited area, and the region of the apex should be gone over carefully, and the ear trained to detect this low-pitched sound. Exercise may bring out this murmur, and I have found that I can more frequently hear it with the patient lying on the left side. When demonstrated, there is little doubt of the diagnosis of structural valvular disease. If it cannot be demonstrated, then a systolic murmur with reversal of the character of the first and second sounds at the apex, dup-lub rather than lub-dup (the second sound may be considerably diminished or absent), together with an accentuation of the pulmonic second sound indicates mitral stenosis. Enlargement of the heart to percussion or by x-ray examination indicates heart disease, but not necessarily valvular disease. In mitral lesions on percussion there is apt to be an extension of the heart border to the upper left, with or without recognizable cardiac enlargement, due to prominence of the pulmonic conus and dilatation of the left auricular appendage. Roentgeno-

graphic examination shows a prominence of the second and third curves of the left border of the heart (pulmonic conus and left auricular appendage) and when the heart is viewed in the right oblique position, dilatation of the left auricle, which lies entirely posterior to the heart in the anteroposterior view except for the appendage, may be seen. These findings may be present in the absence of any recognizable increase in the diameters of the heart as usually determined in the anteroposterior view. Should all other evidences of heart disease mentioned above be absent, in my opinion a systolic apical murmur in a child suspected of rheumatic disease should still be viewed with suspicion for some time to come; often other signs develop later or the murmur may disappear. This, however, does not imply that any restrictions should be placed upon such a child if it be otherwise in good health. It should be remembered that a pure mitral insufficiency is an exceedingly rare valvular lesion. I have never seen an instance proved at autopsy; however, it has been reported.

#### BACTERIAL ENDOCARDITIS

It is not my purpose to discuss this subject at any great length. Adequate descriptions may be found in any textbook on medicine or heart disease. I do wish to stress that the subacute form of bacterial endocarditis may have a very insidious onset. A girl of eight was brought into the hospital following a left hemiplegia occurring suddenly the evening before. She had attended school that day. There was no definite history of illness of any kind preceding the hemiplegia, but the child had been tired, unusually quiet, and had avoided play for some days. An obvious mitral stenosis was detected, and *Streptococcus viridans* was cultured from the blood. This child lived for a year and during that time had an embolic occlusion of her anterior tibial artery and emboli elsewhere. When blood cultures are negative, rapidly developing valvular lesions, a septic type of temperature curve, enlargement of the spleen, clubbing of the fingers, petechiae and the occurrence of embolic phenomena are of the greatest importance in arriving at a correct diagnosis. The retinal and conjunctival arteries should always be examined for hemorrhages of embolic and petechial origin and the occurrence of exquisitely

sensitive points in the fingers and toes with or without tumefaction are significant of small emboli. Recurrent attacks of pain in the left upper quadrant of the abdomen frequently accompany infarction of the spleen. Patients with congenital or rheumatic heart disease are particularly prone to develop such infective endocarditis.

#### PERICARDITIS

Large accumulations of fluid in the pericardial sac are not difficult to recognize from the physical signs and x-ray. Such effusions may be almost symptomless, and the presence of symptoms depends upon the amount of interference with the diastolic filling of the heart. On the other hand, small effusions which accumulate rapidly and before the pericardium has stretched may produce striking symptoms such as dyspnea, paradoxical pulse and cyanosis, and it is not uncommon to see such symptoms disappear, even though the physical signs indicate an increasing amount of fluid, perhaps to reappear again when the pericardium is greatly distended. Daily record of the measurements of the heart should be kept, and a steady increase in the size is of the greatest importance in the diagnosis. Friction rubs are usually present at some time and may persist throughout. The heart sounds become more difficult to hear, and it is very helpful if the apex beat can be palpated far inside the border of percussion dulness. The percussion dulness at the base of the heart is broadened and may diminish in extent on changing the patient from the prone to the upright position. Physical signs of atelectasis of the lung may occur on the left at the angle of the scapula. The x-ray reveals a general enlargement of the heart shadow with an obliteration of the usual demarcations between its chambers.

Effusions of less than several hundreds of cubic centimeters cannot be recognized by physical signs or x-ray. This is of no great importance except in those cases in which the effusion is purulent. It is of the greatest importance to recognize such cases of pericardial abscess early, for in general the sooner drainage is instituted the better chance the patient has to recover. In any illness in which a purulent pericarditis may occur, such as pneumonia, empyema, etc., pericardial friction rubs should be watched for as the earliest and often the only definite indication of pericardial involvement. In these cases

the temperature begins to run a septic course. The electrocardiogram may present suggestive evidence and when this is the case it is generally noted that the ST segments take off high, usually in all leads (Fig. 86). In the nonpurulent forms pericardial tapping is rather infrequently necessary to relieve symptoms, except in those of tuberculous origin. When purulent pericarditis is suspected, tapping may be resorted to for diagnosis. Because of adhesions or pocketing of the effusion, a dry tap may result. If within several days it has not been

Fig. 86 —Purulent pericarditis complicating pneumonia. Note very high take-off of ST segments in all leads.

possible to make the diagnosis certain, and if there is strong evidence of pericardial abscess, or if the diagnosis of purulent pericarditis is reasonably certain without tapping, the pericardium should be opened surgically and drainage established.

As a result of any inflammation of the pericardium adhesions between the visceral and parietal layers are prone to occur. These do little harm unless tight bands constrict the auricles or orifices of the great veins, or the scar tissue contracts so that diastolic filling of the heart is impeded, or in addition to the obliteration of the pericardial cavity, the peri-

cardium is adherent to the mediastinum, pleura and diaphragm. Under this last circumstance great hypertrophy of the heart and eventual failure result. The first two types are of great interest since they lead to increased venous pressure, and stasis in the liver resulting in cardiac cirrhosis and ascites. Suggestive signs of chronic pericarditis are systolic retraction of the interspaces, failure of the axis of the electrocardiogram to change with change in the position of the patient, and on x-ray examination irregularities in the contour of the heart. failure of the heart to descend with inspiration, and but slight difference in the systolic and diastolic size of the heart may be noted. In the constrictive type of chronic pericarditis there is often no cardiac enlargement.

### THE DIAGNOSIS AND TREATMENT OF OTITIC MENINGITIS

THE most common cause of meningitis, excluding the meningococcic and tuberculous forms, is otitic infections. Otitis media is, therefore, a serious infection, primarily because of its complications. Prevention is the best treatment, and careful, understanding observation of every middle ear infection will lead to earlier recognition of the serious sequelae.

The onset of an intracranial complication following a middle ear infection may develop almost immediately after the appearance of the otitis, or it may run a subacute course with relatively few symptoms other than draining ear, and a complication will become manifest at the time the patient is thought to be out of danger. In infants, the ear infection may easily be overlooked until after meningeal invasion has occurred. The course which a middle ear infection may take depends upon the organism, its virulence, and the route of infection which it follows in the temporal bone. The infection may involve the labyrinth, the pneumatized mastoid cells, or the petrous pyramid. From these foci the infection may extend along thrombosed and infected vessels in the bone into the subarachnoid space and brain, and by direct invasion of the leptomeninges from the labyrinth. If the mastoid cells or petrous pyramid become infected, there may be a gradual necrosis of bone and dura, with extension of the infection into the subarachnoid space, brain, or lateral sinus. Therefore, the intracranial infection may be rapid when it travels by way of the labyrinth or infected vessels, and more deliberate when extension occurs through bone and dura. When the mode of ex-

tension is retrograde through the vessels, there may be a rapid intracranial complication without any warning signal. Infections in the labyrinth produce signs of labyrinthine irritation such as vertigo, vomiting, and nystagmus. When the infection takes a more deliberate route directly through bone, the patient usually shows evidence of definite mastoid infection, with pain and swelling of the ear and skin over the mastoid process and persistent discharge from the ear. However, this external evidence may be lacking in some mastoid infections and usually when the petrous pyramid is infected. Once an infection is thought to be present in the temporal bone, procrastination concerning operation may be the cause of an intracranial complication.

The intracranial complications which may follow middle ear infection are meningitis, brain abscess, infective sinus thrombosis, epidural abscess, involvement of cranial nerves by local meningeal reaction, such as described by Gradenigo,<sup>1</sup> and nonsuppurative encephalitis. Occasionally the facial nerve may be paralyzed by necrosis of bone in the region of the facial canal.

#### DIAGNOSIS

Any inflammatory reaction of the meninges may be termed a meningitis, but the fundamental differential is whether the meningeal reaction is sterile or whether it is due to the actual presence of bacteria in the subarachnoid space. A patient may have all the clinical signs of meningitis with a pessimistic outlook only to find that the patient makes an uneventful recovery.

The appearance of symptoms indicating meningeal invasion in a patient with an ear infection should be recognized as early as possible. Headache and mild rigidity of the neck, together with some degree of febrile rise are the earliest symptoms. It is during this period that eradication of the focus may be possible by operative procedure on the mastoid bone. If a mastoid operation has already been done the symptoms may indicate that a walled-off focus was not exposed in the original operation. The impression that the patient is doomed because of these early symptoms is entirely unwarranted, because it is often at this stage that the patient has a cellular reaction

in the meninges without actual invasion by bacteria. As the infection spreads through bone to the epidural surface, there is a reactive process in the dura which attempts to wall off the infection with the formation of an epidural collection of pus. If this is not drained, the inner wall of the dura becomes involved in the extension and again inflammatory reaction is thrown out in advance of bacterial invasion, producing a sterile localized reaction of the leptomeninges. If the spinal fluid is examined at this stage, the cerebrospinal fluid pressure may be slightly increased and microscopic examination will show the presence of a few up to several thousand cells per cubic millimeter. The fluid should be cultured immediately and after culture the fluid centrifuged and smears made to determine the presence of bacteria. In this early stage of sterile meningeal reaction, no time should be lost in attempting to find and eliminate the focus of infection. If operation has previously been done, a second exploration should be considered in the hope of finding a walled-off focus which was not removed at the first operation.

Within twenty-four to forty-eight hours after the initial symptoms of headache and mild rigidity of the neck, the temperature begins to rise rapidly to a level around 104° F. to 105° F., the pulse becomes rapid, the cervical rigidity becomes increased, headache is severe, the patient becomes very restless with later development of delirium, there is a generalized hyperesthesia over the entire body, the Kernig sign is positive, and there may be cranial nerve palsies secondary to the meningeal reaction. At this stage, examination of the spinal fluid gives every indication of the actual presence of organisms in the subarachnoid space. The cell count ranges, as a rule, from 1000 to 5000, and in some instances may reach 35,000 to 40,000. The globulin is increased, the total protein ranges from 75 to 150 mg. per cent, and there is marked reduction or absence of spinal fluid sugar, and decrease in spinal fluid chlorides. The spinal fluid pressure usually ranges from 200 to 400 mm. of water. The cytology of the spinal fluid shows a predominance of polymorphonuclear leukocytes and smears show the presence of organisms.

In a report by Neal, Jackson, and Applebaum<sup>2</sup> on 231 cases of meningitis following otitis media and sinusitis, 121 were

due to streptococci, 75 to pneumococci, 20 to the influenza bacillus, and the remaining 15 to staphylococci, streptothrix, *Bacillus coli*, *B. friedländeri*, and torula.

### TREATMENT

The treatment and prognosis depend upon whether the meningitis is sterile or infective, and on the organism. Cultures should be taken from the ear at the time of paracentesis and from every mastoid operation so that if meningitis subsequently develops, the organism causing the ear infection will be known in case the spinal fluid is sterile. In all cases of sterile meningitis, the mastoid should be operated upon immediately, so that drainage may be instituted at the source of the infection. Spinal drainage should be done once or twice daily until clinical improvement occurs and the spinal fluid approaches normal. Hypotonic glucose, 0.45 per cent, from 500 to 1000 cc., given an hour before drainage will increase the flow of cerebrospinal fluid. By early recognition of the preinfective or sterile stage of meningitis, infective meningitis can often be prevented.

Recoveries from infective otitis meningitis have been reported from time to time, but this is accepted as a rarity. Dwyer<sup>3</sup> states that he has seen 367 cases of meningitis, with 18 recoveries. In a series of 623 cases of meningitis, excluding meningococcic and tuberculous types, Neal, Jackson, and Applebaum<sup>2</sup> state that 16 patients recovered. Of these, 121 cases were streptococcic infections due to otitis media, mastoiditis, and sinusitis, with 9 recoveries.

The recent use of para-amino-benzene-sulfonamide in the treatment of streptococcic infections<sup>4, 5, 6, 7</sup> is most encouraging. Approximately 50 per cent of all otitic meningitis is due to hemolytic streptococci, and if treatment is instituted early, recovery may be expected in this type in the majority of cases. Too few cases have been treated with the drug to arrive at definite conclusions, but in a series of 6 cases of hemolytic streptococcic meningitis and 2 cases of sterile meningitis secondary to streptococcic mastoiditis,<sup>8</sup> all recovered except 1. The following case illustrates the course and treatment of an otitic hemolytic streptococcic meningitis with recovery.

S. B., white male, age seven, was admitted to the South Baltimore General Hospital on March 2, 1937. On February 25, 1937, the child had earache on the left side, with purulent discharge from the ear on the following day. Later in the afternoon the drainage from the ear ceased and a paracentesis was done. The child was sluggish, complained of headache, and was feverish. On March 2 he was very drowsy and was found to have marked cervical rigidity. The examination on admission showed mild delirium and marked rigidity of the neck. The skin was flushed and hot. A purulent discharge was present in the left external auditory meatus. There was some swelling over the mastoid tip with tenderness. The deep reflexes were present and active. The Kernig sign was positive.

The patient was seen by Dr. Nathan Snyder and the diagnosis of mastoiditis with meningeal irritation was made. A left simple mastoidectomy was done and the mastoid cells were found to be necrotic and filled with a thin purulent exudate. The following morning a spinal fluid examination was done by Dr. Louis McIlhenny, and the fluid was found to be cloudy, contained 13,760 cells, was under a pressure of 380 mm. of water, smear showed gram-positive cocci, and after culture a hemolytic streptococcus was identified. The patient was seen by Dr. Richard G. Coblentz and treatment was begun with sulfanilamide (para-amino-benzene-sulfonamide). The temperature course is shown in Fig. 87 and the treatment and laboratory findings are shown in Fig. 88. The patient showed an immediate improvement in the spinal fluid findings, but his clinical course was very stormy. On the fourth day after treatment was begun he was definitely improved, showed less rigidity of the neck, and was more alert. On March 13 his temperature rose to 105° F., the mastoid incision was widened for better drainage, the patient appeared very toxic, and his neck was still quite rigid. On March 13 and 16 small transfusions were given. From this point on there was slow but gradual improvement with a gradual decline of the temperature by lysis, and after April 1 the temperature did not exceed 100° F. rectally. The drainage from the mastoid incision and ear gradually decreased and when he left the hospital on April 18 the wound was healed and the discharge from the ear had ceased entirely. Three weeks following discharge from the hospital, he was again examined and was found to be in excellent health, was gaining weight, and had no complaints.

From Fig. 88 it will be seen that in the treatment the drug was administered by the oral, subcutaneous, and intrathecal routes. At the beginning of treatment in meningitis, the oral administration cannot, as a rule, be relied upon because of the uncooperative state of the patient. The calculated daily dose should be given in two infusions of 1 per cent solution in normal saline, eight to twelve hours apart. In preparing the solution, the salt solution should be brought to the boiling point and after cooling a few degrees, the powdered sulfanilamide added slowly. No further sterilization is necessary. The

Fig S7.—Chart showing temperature, pulse and respiration. (Continued on p. 1319.)

Concerning the intrathecal administration, the exact requirements have not yet been determined. In 7 of the 8 cases of streptococcic meningitis treated by me, the drug was given intrathecally once a day in a dose ranging from 25 to 50 cc. of a 1 per cent solution. This was continued until at least 3 negative spinal fluid cultures were obtained. In the case just described, 5 injections were given after the spinal fluid became negative, because of the stormy course. However, in 1 case of the series, only 1 intrathecal injection was given and the patient made a prompt recovery.

In computing the dose, an average of 1 Gm. per 20 pounds of body weight every twenty-four hours has been advocated by Long.<sup>6</sup> Children will tolerate much larger doses, but whether this is necessary has not yet been determined. In two children weighing 50 pounds, 6 Gm. a day were well tolerated.

The majority of patients receiving the drug will develop varying degrees of cyanosis, but this clears up rapidly after administration is stopped. A moderate anemia may develop after prolonged use, and in patients who have an idiosyncrasy to the drug, an occasional severe hemolytic anemia may occur, as shown by the excretion of urine of port-wine color. If acidosis occurs, alkalis should be administered. Therefore, during the treatment the hemoglobin, red count, carbon dioxide combining power, and urine should be carefully watched.

As previously stated, the treatment of otitic meningitis depends upon whether it is sterile or infective and the causative organism. The preliminary work on streptococcic meningitis indicates that a fair percentage of recoveries can be expected when treated by sulfanilamide, so that if the original otitis media or mastoiditis is known to be due to hemolytic streptococci, this drug should be employed. If the causative organism in the original infection is not known and the spinal fluid shows the absence of organisms, it would seem worth while to use sulfanilamide because of the high percentage of streptococcic infections in otitic meningitis. In dealing with streptococcic meningitis where sulfanilamide therapy is used, the advisability of doing a mastoidectomy is an open one. The first case I treated had a severe mastoid infection, but the operation was deferred until after the spinal fluid cultures were negative. In another case, the mastoid was not operated upon

and the prompt cessation of discharge from the ear and the recovery of the patient suggest that mastoidectomy may be unnecessary in hemolytic streptococcic infections.

Fig. 88.

If the original otitic infection is due to an organism other than hemolytic streptococci and the meningitis is still in the sterile stage, mastoidectomy should be done as early as possible. By so doing, the entrance of organisms into the subarachnoid space may be prevented.

If the meningitis is of pneumococcic etiology, sulfanilamide may be tried, but my experience in 2 cases is discouraging. Both of these patients showed a clinical course modified from the usual untreated pneumococcic meningitis, but death occurred in both cases. Patients with pneumococcic meningitis may recover occasionally with specific antipneumococcic serum and it may be worth while to combine serum and sulfanilamide. However, no satisfactory treatment for pneumococcic meningitis has yet been devised.

Approximately 20 per cent of all otitic meningitis is due to organisms other than streptococci and pneumococci. Since there is no specific treatment, daily spinal drainage and general supportive treatment should be employed.

## CLINIC OF DR. EDWARD A. LOOPER

### BALTIMORE

---

### INFECTION OF THE NASAL ACCESSORY SINUSES IN CHILDREN

FREQUENT colds associated with nasal discharge generally mean infection of some of the accessory sinuses. It is now generally recognized that a so-called "common cold" which does not clear up in two weeks' time has become complicated by invasion into some of the sinuses and if left untreated will result in serious disease. This is particularly true in infants and young children, for we know that the constantly "running" nose in a child demands definite attention if the child's future health and development be given the serious consideration it deserves. Children with infected sinuses are irritable, anemic, undernourished and present all the symptoms associated with an active focus of infection. Furthermore, such infections retard the development of the sinuses themselves so that a condition is left for the continuance of a chronic disease which might have been prevented if early treatment had been instituted.

It is a common practice to attribute all chronic colds and all cases with nasal discharge, regardless of location, character or amount of secretion, to diseases of the tonsils and adenoids. It is often taken for granted that this is the only factor to be considered, while in fact the true source of the infection may be in the paranasal sinuses. The importance of investigating this field is impressed upon us when we frequently encounter children who have had their tonsils and adenoids removed, but who do not get the desired relief of their symptoms. They give a history of colds being as frequent and the nasal discharge as constant and as severe as before operation. The operation is frequently considered as an unjustifiable pro-

cedure, the results being unsatisfactory to the patient and embarrassing to the surgeon. A situation of this kind can be avoided if more attention is paid to the sinuses before the tonsils and adenoids are removed. In all cases of children with inflammatory lesions around the nose and throat, where the nasal symptoms predominate, the sinuses should be examined. Where there is a great deal of sneezing, congestion of the turbinates, constant colds with thick profuse nasal discharge, a careful investigation of the sinuses is called for.

Fig. 89.—Orbital abscess from an infected antrum. In an infant three weeks of age.

If the diagnosis is correctly made, treatment can be properly instituted and the results will be satisfactory.

While children are not as susceptible to diseases of the sinuses as adults, the condition is frequent enough to require careful consideration. In fact, the subject requires more attention than is generally given to it by rhinologists. Haike<sup>1</sup> made an autopsy study of 394 cases of children. He opened the sinuses of 62 cases and found 52 of this number diseased. The ages were from nine months to thirteen years. Forty-

seven cases had an infection of the maxillary antrum, 2 of the sphenoids and 3 had an involvement of the ethmoid cells. Dean and Armstrong<sup>2</sup> investigated the sinuses in a group of children presenting the common symptoms of infected tonsils and adenoids. One hundred and forty-five cases were examined, and of this number 65 showed some definite involvement of the sinuses. In a similar group of cases White<sup>3</sup> made x-ray studies of 50 children who had been admitted to the hospital for tonsillectomy and adenoidectomy and out of the 50 cases 41 showed pathologic sinuses.

Apparently one reason why this condition is not suspected more frequently is that there is still a prevalent opinion that the sinuses in children are so undeveloped that they do not play an important part in the etiology of early nasal in-

Fig. 90.—Severe orbital abscess in a child six weeks old.

fections. In an effort to clarify this misconception, I will briefly mention our present knowledge of the anatomic construction of the sinuses in infants and children. Considerable work along this line has been accomplished by Onodi<sup>4</sup> who has made an extensive anatomic study of 102 skulls. The material was obtained from fetuses six and a half to eight months, from the newborn, and from children one to nineteen years of age. Since his work, our knowledge of this subject has been further supplemented by the valuable investigations of Davis<sup>5</sup> and more recently by the contributions of Schaeffer.<sup>6</sup> The general opinion is that the frontal sinus makes its appearance from the end of the first year to the beginning of the third year.<sup>7</sup> It develops slowly and is about the size of a pea between the sixth and seventh years. From the seventh to the

ninth year it is recognized as a distinct cavity. The maximum development is reached during the nineteenth year, when it measures from 16 to 21 mm. in height and from 21 to 24 mm. in width.<sup>8</sup> The sphenoid sinus is merely a faint depression in the body of the sphenoid bone at birth. Its real development begins at the end of the fourth month and generally increases in size until the sixteenth year. The ethmoid cells are present in the newborn, as shown by Curran<sup>9</sup> who dissected fetuses from three and one-half months to birth. They develop in size with advancing years until puberty. The

Fig. 91 —Infected ethmoids. Child one month old.

maxillary antrum is most frequently infected in the child, as it has the earliest and greatest development. According to Gegenbaur,<sup>10</sup> "The first rudiment of the maxillary antrum is the first to appear, being seen even before the middle of fetal life, but it does not attain its complete development until comparatively late, nor does it show any considerable growth before the second year of childhood." At birth it occupies a small space to the inner side of the orbit.<sup>11</sup> The subsequent development is downward, assuming its full shape after the eruption of the permanent teeth. The maximum development

is attained between the fifteenth and eighteenth years. So we find the maxillary antra and ethmoid cells present at birth, while the frontals and sphenoids make their appearance before the third year. Therefore from an anatomic standpoint the sinuses in early life are sufficiently developed to be taken into consideration in pathologic processes. It is true that the sinuses in children are not always perfectly developed, for even in the adult we know of no structure in the human body which is subject to such wide variations in size, structure, location and development as the accessory sinuses.

In the early years of childhood the upper respiratory tract is particularly susceptible to infection and is generally involved in most of the exanthematous diseases. In practically

Fig. 92.—Infected ethmoids. Orbital abscess, age three years.

every case of measles, whooping cough, diphtheria and scarlet fever, severe reactions are produced in this area. We are always on the alert for ear involvement following these diseases, but do we pay sufficient attention to nasal complications?

The sinuses are lined with mucous membrane similar in structure to that of the eustachian tube, and by the process of continuity can be readily infected. The numerous recesses and cavities adjoining the nasal fossae produce an ideal location for the implantation and development of organisms. If bacteria are placed upon the smooth unobstructed mucous membrane of the mouth we know that they will be eliminated by the normal douching action of the oral secretions as demonstrated by Bloomfield's<sup>12</sup> work. However, when they lodge

in obstructed crevices like the tonsillar crypts, reduplicated nasal mucous membrane or sinus cavities, they remain for a

Fig. 93.—Orbital abscess. Ethmoid infection. Age nine years.

Fig. 94.—Orbital abscess. Frontal and ethmoid infection

much longer time. If the body resistance is below normal, or if the predominating organisms are of a very virulent strain, the defensive action of the tissues may not be able to resist

infection. When the sinuses become extensively infected, eradication of the disease is extremely difficult. Congested nasal mucosa, hypertrophied turbinates, septal deviations, small nasal cavities, all interfere with ventilation and drainage, thus prolonging a condition which could be easily eradicated in a more accessible environment.

### DIAGNOSIS

The diagnosis of infected sinuses in children is more difficult than in adults, because subjective symptoms cannot be expressed. In older children, indefinite pains around the head and face with headache may be complained of, although these symptoms are not always present. The history is very important. It is well to know if the child has had measles, diphtheria, whooping cough and scarlet fever, for White<sup>13</sup> found 32 cases in 50 of his series with infected sinuses who gave a history of childhood diseases. Twenty-nine of these gave a history of whooping cough, 3 had diphtheria, 8 had mumps, while 18 gave a history of chronic colds. Onodi<sup>14</sup> tabulated 23 cases of the earliest reports of infected sinuses in children and all of these were complications of scarlet fever. Any chronic cold with nasal discharge should arouse our suspicion of infection of these structures. Sneezing, headache, irritability and depression are considered very important symptoms by Byfield.<sup>15</sup> Mouth breathing and coughing are also significant signs.

In examination, the nasopharyngoscope is a help, but the procedure is rather difficult. Diagnostic puncture of the antrum with bacteriologic study of the secretion may be resorted to in obscure cases. This procedure has been used successfully by Dean and Armstrong.<sup>16</sup> Transillumination is unreliable, as Skillern<sup>17</sup> points out, and in my own experience has been misleading instead of being of actual diagnostic value. x-Ray examination is our greatest aid, but the plate must be made by a skilful roentgenologist and the interpretation must be correlated with clinical findings. Any child presenting a majority of symptoms mentioned or in any case where there is cause to suspect sinus involvement should certainly have the benefit of an x-ray examination.

During the past few years I have had occasion to see a

number of cases, young children from three to twelve years of age, who have had their tonsils and adenoids removed without their original symptoms of infection clearing up as had been expected. They came in for relief of colds, nasal discharge and mouth breathing. Most of them had had their tonsils and adenoids removed from two to three years previous to this examination. A summary of the important points in the cases presented follows.

### CASE REPORTS

**Case I.**—A. N., aged seven, had tonsils and adenoids removed three years ago in order to clear up persistent nasal discharge. As the result of the operation there was some improvement in the symptoms for a while, but the nasal discharge continued. At the present time there is a great deal of thick mucopurulent discharge in each nostril. A quantity of this drains postnasally causing some pharyngeal irritation. The tonsillar fossae are clean and there are no adenoids. The turbinates are congested and enlarged. x-Ray examination shows clouding of the antra, also some blurring in the ethmoid cells.

**Case II.**—J. M., aged seven and one-half, came for the relief of constant nasal discharge. Tonsils and adenoids were removed two years ago. At the present time there is no tonsillar tissue remaining, no adenoids found. The infection is confined to the nasal cavity. x-Ray examination shows marked clouding of both antra.

**Case III.**—E. G., aged seven. Tonsils and adenoids were removed in 1919. Since operation the patient has had frequent colds and nasal discharge. At the present time there is a great deal of thick mucopurulent postnasal discharge, which produces a great deal of sniffing and coughing. There is no evidence of any remaining tonsil and adenoid tissue. x-Ray examination shows clouding of both antra and some haziness of ethmoids and frontals.

**Case IV.**—I. S., aged ten, had been treated for chronic rhinitis with constant discharge from right nostril. He gave a history of repeated colds. About two and one-half years ago tonsils and adenoids had been removed in an effort to clear up the trouble, but there had been very little relief. Present examination shows a great deal of turgescence of right middle and inferior turbinates. x-Ray examination shows clouding of right antrum. After puncturing the antrum and several irrigations, the infection cleared up and he has since been free of symptoms.

**Case V.**—R. L., aged ten. Patient was referred for investigation of the sinuses as the cause for repeated nasal infections. Two and one-half years ago tonsils and adenoids had been removed but this had little effect on his nasal infection. x-Ray examination shows definite clouding of both antra. There is a great deal of mucopurulent discharge with infiltration of the tur-

binates and mucous membrane. After a simple puncture of the antra and repeated irrigations the infection cleared up.

**Case VI.**—R. L., aged six, had tonsils and adenoids removed three and one-half years ago for relief of repeated colds. Since that time there has been very little improvement in the nasal condition. Examination at this time shows marked hypertrophy of the turbinates with clouding of both antra. This is confirmed by x-ray examination. No remaining tonsil and adenoid tissue was found.

**Case VII.**—R. S., aged thirteen, was referred for investigation for sinuses as a possible cause for repeated attacks of asthma. He has had these attacks since he was a child. They resisted all modern methods of treatment. The diet had been carefully investigated, vaccine had been given, tonsils and adenoids removed, but the symptoms would recur. Nasal examination shows a clouding of the left antrum. After puncturing and irrigating this antrum his local nasal symptoms cleared up and he has had no further asthmatic attacks.

**Case VIII.**—C. H., aged six, for the past three years has had intermittent attacks of asthma. Colds have been frequent and there has been considerable nasal discharge. Tonsils and adenoids were removed and an effort was made to clear up the trouble, but there was little improvement in the symptoms. He was referred for nasal treatment. On examination there was marked clouding of left antrum. The right antrum was small and outlines indistinct. Ethmoids were infected and there was a great deal of enlargement of turbinates.

**Case IX.**—D. L., aged eight, gave a history of repeated colds, a great deal of sneezing and considerable nasal discharge. Tonsils and adenoids had been removed two years previously. Since operation colds have been as frequent, and there has been little improvement in his condition. On examination of the sinuses there was marked clouding of the right antrum. Under local treatment the infection was completely cleared up and the patient has been free from colds for several months.

**Case X.**—F. R., aged fourteen, came for relief of repeated attacks of colds. Tonsils and adenoids were removed six years ago. A great deal of mucopurulent discharge was present in the nasopharynx. Examination of nose showed a chronic ethmoid infection and clouding of both antra. Symptoms completely cleared up under local treatment.

### COMPLICATIONS

Orbital abscess is one of the most frequent, and often the most dangerous complication of accessory sinus disease. A definite abscess is characterized by edema of the affected eye, lids and surrounding tissue. The eyeball is forced out and there is immobility of the extra-ocular muscles. With pus

formation, there is elevation of temperature and increased leukocytosis. If the pressure is not relieved by free drainage, vision may be affected. Some of these cases occur in early life. Case I shows an infant three weeks old with an infected antrum, complicated by orbital abscess. This is an unusual case but it demonstrates the danger of this complication even in young children. Case II is of a child six weeks old, with an infected antrum and orbital complications.

Meningitis and brain abscess is a very serious complication of sinus disease and usually results fatally. Fortunately it does not occur in many cases. The complications associated with any chronic focus of infection may be present with accessory sinus diseases in children. Anemia, loss of weight, low unexplained temperature and gastro-intestinal symptoms are frequently present, so that any such group of symptoms calls for investigation and treatment of the sinuses.

#### TREATMENT

The simple acute infections of the accessory sinuses in children respond very favorably to treatment. Usually small doses of calomel with a few days' rest in bed is all the general treatment required. Locally, the mucous membrane should be kept clean with some warm cleansing spray of normal saline or dilute Dobell's solution, after which some 20 per cent argyrol should be applied. The most convenient way to apply this to the nose is to place the child on his back and with an ordinary eyedropper drop from 15 to 20 drops in each nostril. Most of the cases clear up without complications. In the chronic cases the eradication of the infection is more difficult. If the tonsils and adenoids have not been removed it is advisable to get them out in order to clear up as many foci of infection as possible. Dean and Armstrong<sup>18</sup> found that 80 per cent of their cases cleared up after the tonsils and adenoids had been removed.

Local treatment consists of keeping the infected surface as clean as possible. Suction is very valuable in this condition. for many crevices can be evacuated which could not otherwise be reached. Warm saline sprays are very cleansing, soothing and stimulating to the mucous membrane. After this, it is helpful to make applications of 2 per cent silver nitrate or 20

per cent argyrol. This should be followed by some emollient spray. Young children can be best treated in a hospital. The treatment can be carried out much more satisfactorily if the child is away from its parents. Some cases are helped by the administration of vaccines. A few cases require conservative operative procedures, such as puncture and irrigation of the antra. Only in very exceptional cases is it necessary to do any radical operations.

### SUMMARY

1. All children who have chronic colds with predominant nasal symptoms, such as profuse nasal discharge, stuffiness of the head; mouth breathing and asthmatic attacks, should have a careful investigation of the sinuses.

2. Cases in which tonsils and adenoids have been removed for focal areas of infection, and the symptoms have not cleared up after operation, should be suspected of harboring an infection of the accessory nasal sinuses.

3. Neglected treatment of early infection of the sinuses in children predisposes to chronic infection which may lay the foundation for serious complications in later life.

4. Nasal colds in children should be treated as an important disease. Careful investigation should be made as to their etiology and diagnosis.

5. The proper treatment of infected sinuses in children gives gratifying results. The general health of the patient is improved. They take on weight, develop more rapidly and give every appearance of being greatly benefited. Most of the cases can be cured by local treatment, for only a small number require operative procedures.

FROM THE DEPARTMENT OF PSYCHIATRY, UNIVERSITY OF  
MARYLAND AND THE MENTAL HYGIENE SOCIETY OF  
MARYLAND

---

### THE EFFECT OF HEAD INJURY ON THE BEHAVIOR AND PERSONALITY OF CHILDREN: A STUDY OF 20 CASES

#### INTRODUCTION

MUCH has been written on the subject of head injury in children. Ireland<sup>15</sup> who studied 80 children with fractured skulls, covered the literature on that topic quite adequately. Blau,<sup>5</sup> who presents a study of 22 children with mental sequelae following head trauma, also covers the literature on this aspect very thoroughly. In recent books there are excellent discussions of this subject in Kanner's *Child Psychiatry*<sup>16</sup> and Montgomery's chapter in *Practice of Pediatrics*.<sup>20</sup> By far the most complete review of the literature is found in an article by Strauss and Savitsky.<sup>23</sup> It is not the purpose of this paper to duplicate these studies, but primarily to attempt to clarify the question of etiology.

#### PRESENT STUDY

The 20 cases selected for this study comprise all the children who have had head injury and who were seen by the author in the past six years (1931 to 1936 inclusive). In this period the author examined 752 children referred to a child guidance clinic. Eight cases were selected from 232 children seen in the Mental Hygiene Clinic of the Cleveland Board of Education. Twelve cases were selected from 520 children seen in the Baltimore Mental Hygiene Clinic.

There is a marked divergence of opinion among authors as to the incidence of sequelae after head injury. Ireland<sup>15</sup> fol-

lowed his cases for a period averaging thirteen months after skull fracture and found that 11 per cent showed serious sequelae, mostly of a neurologic nature. Beekman<sup>3</sup> made a follow-up study of 331 children with head injury. He found temporary sequelae in 23 per cent but permanent symptoms in less than 5 per cent. These findings are far more encouraging than those of early writers, such as English.<sup>8</sup>

There are no figures exactly comparable to the author's incidence of 2.4 per cent (20 cases in 752 consecutive child guidance clinic children). Kasanin<sup>17</sup> studied 120 children diagnosed as having psychopathic personalities and found that 13 (10.8 per cent) "had serious brain injury during childhood or adolescence." He compared this with a control group of 120 children with different diagnoses. Of these only 2 (1.6 per cent) had had serious brain injury. Healy<sup>11</sup> in a study of 1000 consecutive juvenile delinquents found 21 cases (2.1 per cent) who had suffered a severe head injury. In a later study of 4000 juvenile delinquents Healy<sup>12</sup> found that 3.5 per cent had head injury "with at least a period of unconsciousness." Healy and Bronner<sup>13</sup> in a recent study of 105 delinquents compared with 105 nondelinquent siblings, found a history of severe head injury in 4.7 per cent of the delinquent group and none in the control group.

The author used two criteria for selecting the cases. First, at least two of Kennedy's<sup>18</sup> criteria of severe head injury were satisfied. This resulted in a group of 10 such cases. Second, the child had a mild degree of head injury (scalp laceration or a short period of unconsciousness) on which a parent blamed the child's difficulty. This resulted in a group of 10 cases with a mild degree of injury. It is of interest to note that in only 3 of the 20 cases neither parent blamed the accident for the children's difficulty, and all 3 cases fell in the group with severe injury. In 7 cases (3 of them mild) the parents attempted to sue or did collect money because of the injury.

In describing the group as a whole it is interesting to note that there were 19 boys and 1 girl. In Blau's<sup>5</sup> study of 22 children, 20 were boys. The children ranged in age from six to seventeen years, with the average age about ten and one-half years. They were seen from one month to nine years after the accident. The average interval of time was about

five and one-half years. The group was nearly average in intelligence. Their intelligence quotients (I. Q.), based on the Stanford-Binet test, ranged from 56 to 108. The average was about 89. The group as a whole averaged 2 semesters retarded according to chronological age (ranging from 2 semesters accelerated to 8 semesters retarded). They averaged at grade, however, according to Stanford-Binet mental age (ranging from 4 semesters accelerated to 4 semesters retarded). The brighter children tended to be retarded while the duller ones were accelerated, according to mental age.

### BEHAVIOR AND PERSONALITY

The most characteristic statement regarding children who have suffered from brain injury is that there is a change of character following the trauma. Beekman<sup>3</sup> describes a wide variety of symptoms. He writes, "The symptoms complained of in the sequelae are more often of a subjective or emotional type than those of an objective type. Headache is the commonest complaint and it usually clears up within a year after the accident. Emotional instability is seen frequently. This varies anywhere from mild nervousness to a behaviorism which is a total change from the child's former character. . . . The severity of this change in behavior varied from mild emotional symptoms—'nervousness,' attacks of crying for no apparent cause or slight irritability—to a change in character, where the child became sullen, quarrelsome and incorrigible." Most authors describe explosive outbreaks of temper, with destructive, cruel behavior. Meyer,<sup>10</sup> in an early study of head injury in adult mental patients, called this the "type with explosive diathesis." Healy<sup>11</sup> describes this reaction thus, "The mental changes typically lead to passionate outbreaks and great decrease in the power of self-control and an easy mental fatigability creates lack of continuity of purpose." Strecker and Ebaugh<sup>24</sup> studied 30 children in a psychiatric clinic, who gave a previous history of head injury. Fifteen (50 per cent) showed these explosive outbreaks of temper. Blau<sup>5</sup> calls this reaction chronic posttraumatic behavior disorder and describes them as "asocial, unmanageable and unyielding to any form of training." Of his 22 cases 12 (54 per cent) showed

this behavior. Blau,<sup>5</sup> Kasanin,<sup>17</sup> and Strecker and Ebaugh,<sup>24</sup> point out the similarity of this mental picture with that seen in children after epidemic encephalitis. Bond and Partridge,<sup>6</sup> describing postencephalitic behavior disorders in children, write, "We have found evidence that nothing quite matches it except possibly the traumatic disorders."

Blau<sup>5</sup> classified his 22 cases into four groups, with some overlapping, which accounts for discrepancies in totals and percentages. Six of his cases (27 per cent) showed acute psychoses. Blau states that he can find no reference in the literature to this reaction in children. Twelve of his cases (54 per cent) showed chronic behavior disorders. Five (22 per cent) showed posttraumatic epilepsy. Two (9 per cent) showed cerebral defect and intellectual retardation.

In the present study an attempt was made to classify the cases according to the behavior of the child following the injury. This was difficult as some cases overlapped, that is, they showed behavior of more than one type. This overlapping will account for discrepancies in totals and percentages. In this group there were no cases showing epilepsy or acute psychosis as sequelae.

#### CHILDREN SHOWING NEUROTIC SYMPTOMS

This was by far the largest group in the present series, consisting of 10 cases (50 per cent). The most frequent symptoms found in this group were: "nervousness," 8; headache, 4; enuresis, 4; having many fears, 4; nail biting, 3, and sleep disturbances, 3. The following case is presented to illustrate this type of reaction.

*Case I.—Reason for Referral.*—M. R., a six-year-old white girl, in kindergarten, was referred in November, 1936, to the clinic, two years after her accident. She has many fears and does not play with other children.

*Development.*—Oldest of three children. Birth and development were normal. She was hospitalized a few days

*Diagnosis.*—Gastro-intestinal disorder, erythema multiforme. Six months later she had a discharging ear

*Accident.*—At the age of three years and ten months patient fell from a porch, striking her head on the ground. She vomited for two successive days. She was hospitalized for twelve days. The hospital reports negative findings on a careful neurologic examination. x-Ray of the skull showed a

fracture of the left parietal and temporal bones with no displacement or depression. No spinal puncture was performed. Recovery uneventful.

*Recent Behavior.*—Mother blames most of patient's recent trouble on the accident. Since the accident patient has been nervous, fearful, timid, biting her nails. She cries easily, is afraid of the dark and is frightened by the least noise. She is especially afraid if children (even younger) show any aggression toward her. Thus she is afraid of her three and one-half-year-old half-brother. She has had occasional enuresis. She won't eat unless her mother urges her.

*Home Environment.*—The mother, Protestant, came from an unhappy, broken home. All her brothers and sisters have been divorced. Mother married a Catholic at sixteen years, because the man threatened to kill her if she didn't marry him. She left her husband because he drank so much. She then lived with patient's father but left him when he went with women. She returned to her husband but plans to leave as he still drinks and goes with women.

When drunk he throws up to mother the fact that patient is not his child. Mother induced abortion twice and her husband has been disgusted with her because of this. Patient is afraid of her stepfather when he comes home drunk. During much of this time patient lived with her maternal grandmother.

*Examinations.*—*Physical.*—Several examinations following the accident have been essentially negative.

*Psychologic.*—Stanford-Binet: chronologic age, six years one month; mental age, five years four months; I. Q., 84. Tests ranged from three to seven years.

*Rating.*—Dull normal intelligence.

*Psychiatric.*—Patient describes how her father left after a fight with mother and how mother is trying to force him to buy clothes for patient. Patient is very unhappy with stepfather. He comes home drunk and fights mother and beats patient. Patient is afraid of him. He tells mother he won't keep patient, she will have to leave. Patient wishes she could live with some relative and describes vague fears of men assaulting her.

*Interpretation.*—The patient feels extremely insecure. She is illegitimate, is rejected by her mother, and has moved about a lot among relatives. She is afraid of her stepfather and is extremely unhappy at home. These factors are more important than the head injury in producing her symptoms. The mother needs to use the head injury as a form of alibi.

*Treatment.*—The clinic suggested that patient be placed either with some relatives or in a foster home. As a way of achieving that it was suggested that she first be placed in the children's convalescent school. This has been done and patient has already (two weeks) shown definite improvement.

This neurotic reaction is also illustrated by Cases VI, VII, VIII and IX in the Appendix. Half of this group of 10 cases showed severe head injury. In 8 cases a parent blamed the child's trouble on the injury. In only one instance, however, did a parent attempt to sue for damages.

## CHILDREN SHOWING DELINQUENT BEHAVIOR

This group contained 5 cases (25 per cent). The most frequent symptoms found in this group were: defying authority, 4; stealing, 3; truancy, 3, and running from home, 2. Of these children 3 had been in juvenile court and one in an institution. The following case is presented to illustrate this reaction.

*Case II.—Reason for Referral.*—E. H., a twelve-year-old white boy, in low fifth grade, was referred in January, 1931, to the Cleveland clinic seven years after his accident. He steals from parked cars and gets into a lot of mischief such as riding cars, pulling trolleys off street cars.

*Development.*—Youngest of 4 children. Birth was unwelcome to both parents. Mother was very ill during pregnancy and unhappy because she hated living with her mother-in-law. Birth was prolonged, a breech delivery. Patient was breast-fed three months. In telling this mother explained, "It wasn't because I didn't want to give it to him." Development was retarded. Walked at fourteen months and talked at two years. First teeth came at ten months. Patient had chickenpox severely at three years. Patient had tonsillitis every winter and had coughs lasting most of the winter. Has always been underweight. Mother babies him—won't let him go swimming. She said, "He's my baby and I like to fondle him a lot." Patient slept with mother until he was six years old.

*Accident.*—At five years of age patient was hit by a truck and was unconscious for nine days. He was in the hospital twenty-three days and they diagnosed a transverse, frontal fracture of the skull.

*Recent Behavior.*—Mother claims that ever since his accident patient has been sneaky. He goes with a gang of boys who steal. On two occasions patient was taken to Juvenile Court for stealing. He smokes a great deal. He fights with boys. At school he tries to attract attention. His school work is careless.

*Home Environment.*—Both parents were brought up in unhappy homes. Their parents quarreled, were abusive and separated. Both parents are extremely immature and neurotic. Both parents have had nervous breakdowns. The father has some almost psychotic symptoms. The mother had two nervous breakdowns. Both parents were very disappointed in their marriage. The father deserted for three months before patient's birth. Neither parent wanted any children. For this reason the mother induced abortion many times. She never liked housework and neglected her children.

*Examinations—Physical*—He is 12 per cent underweight, has diseased tonsils, cervical adenitis and thickened ear drums.

*Psychologic*—At eleven years of age patient was given the National Intelligence Test and obtained an I. Q. of 68.

*Stanford-Binet*—Chronologic age, twelve years one month; mental age, eight years two months; I Q. 67.

*Rating.*—Borderline mental defective.

*Psychiatric.*—Patient shows a marked degree of attachment to and dependence on his mother, and hostility toward his father. Says he is his mother's favorite while his father picks on him all the time. He will never marry till his mother dies. Is very anxious to learn to dance so he can dance with his mother before she is too old. He shows a marked degree of feelings of inferiority and relates these to his accident. Since his accident he has never been strong and has been sick a lot. He can't play baseball. Tells how he likes to do stunts and show off. He talked frankly about his stealing.

*Treatment.*—Tonsillectomy was advised. Also placement in a special class for retarded children. The school was asked to help patient build up his self-confidence. The mother was asked to give patient more recreational freedom. Patient was seen several times by the psychiatrist in treatment interviews. During the period of treatment (six months) patient showed definite improvement with no evidence of stealing.

This delinquent behavior is also illustrated by Cases X and XI in the Appendix. Two of this group of 5 cases showed severe head injury. In all 5 cases a parent blamed the child's trouble on the injury. In 2 cases a parent attempted to sue for damages.

#### CHILDREN SHOWING EXPLOSIVE TANTRUMS

This group contained 4 cases (20 per cent). The most frequent symptoms found in this group were: severe, explosive tantrums, 4; attacking adults or children, 4; marked hyperactivity, 2; being unmanageable, 2, and attention-getting behavior, 2. The following case is presented to illustrate this reaction.

*Case III.—Reason for Referral.*—G. C., a six-year-old white boy in high first grade, was referred in September, 1934, to the clinic, two months after his accident. Ever since his accident he has had severe temper tantrums. Parents think he is mentally deranged.

*Development.*—Fourth of 5 children. Birth and development normal. Breast-fed over a year. At first mother claimed he was an easy child to manage and normal until his accident. In a later interview she said patient has always had nocturnal and diurnal enuresis. He has always been nervous and hyperactive. Physicians have treated him for nervousness and one doctor diagnosed chorea. When four years old patient fell off a wagon and bumped his head. He was unconscious and vomited when he woke up. Mother was frantic then and dates his nervousness from the first fall.

*Accident.*—See above for accident at four years. At six years seven months of age patient was hit by an auto. Immediately after the accident patient became so "wild" it took 4 men to get him into a truck which took him to the hospital. The hospital diagnosed concussion and lacerations of head

and shoulder. At the hospital he was unconscious for half a day and in a daze for two days. He was in the hospital three weeks.

*Recent Behavior.*—At first mother claimed that all of patient's trouble was since the last accident. Later she admitted difficulties before it (see above). Since patient's return from the hospital he has had violent temper spells three and four times a day. These occur when he can't have his way. In these he throws himself on the floor and screams, or he attacks his mother or brothers. The school does not complain about his behavior. The mother fears a clot has formed on the brain and she fears he will go crazy, have epilepsy or die. The father fears patient will kill someone. Mother is asking agencies how she can sue for compensation.

*Home Environment.*—The father had nocturnal enuresis till late. He always disliked school. He is somewhat shiftless and did not support his family well even before the depression. He has been on relief most of the depression. The mother is a dull, ignorant person who is extremely upset over patient's condition. Mother's fears are augmented by the fact that one of her children died at the age of one year following a fall.

*Examinations.*—Physical and neurologic examinations were essentially negative.

*Psychologic.*—Stanford-Binet: chronologic age, six years nine months; mental age, six years two months; I. Q., 91. Tests ranged from five to nine years.

*Rating.*—Average intelligence.

On 3 performance (manual) tests he gave an average performance. At the end of the test he suddenly burst out crying and ran to his mother.

*Psychiatric.*—Patient was extremely resistive and cried most of the time. He said his mother was afraid to bring him to the clinic for fear we might do something to him. Also his mother won't let him go to school because she is afraid—he doesn't know why.

*Interpretation.*—The patient may have suffered from brain injury resulting in increased irritability but it is felt that the major part of his difficulty is based on his mother's extreme anxiety regarding patient. Patient reflects this by feeling marked anxiety himself.

*Treatment.*—Patient was sent to a children's convalescent school with the recommendation that he remain six months. He improved so markedly that he was sent home after two months. His improvement lasted only two or three weeks after his return home. Treatment at the clinic was suggested but mother has consistently broken appointments.

This tantrum behavior is also illustrated by Cases XII and XIII in the Appendix. Only one of this group of 4 cases showed severe head injury. In 3 cases a parent blamed the child's trouble on the injury. In 3 cases a parent attempted to sue for damages.

## CHILDREN SHOWING MENTAL RETARDATION

This group contained 5 cases (25 per cent). The symptoms complained of were: poor school progress (or failing work), 5; inability to learn, 2; reading disability, 2. Four of this group of 5 cases showed severe head injury. In 4 cases a parent blamed the child's retardation on the injury, and in 2 cases a parent attempted to sue for damages.

Blau<sup>5</sup> presents 2 cases of mental deterioration following head injury. Strecker and Ebaugh<sup>24</sup> present 6 cases and Healy<sup>11</sup> presents 1 case. In all these cases, as well as those in the present study, mental efficiency was impaired as evidenced by poor school work. However, the evidence for an actual change in mental ability is far from convincing. This point cannot be settled until more cases are reported where a child was given psychological tests before and after the head injury. The author was able to find in the literature only one report of a child who had been tested before and after a head injury. Hardwick<sup>10</sup> describes a fourteen-year-old boy who was given the Stanford-Binet test before and after a severe head injury. She did not give the results but writes, "In general his reactions were slower but more accurate than before."

In the present study the average tested intelligence of these 5 children (I. Q., 87) was practically the same as the average for the entire group (I. Q., 89). All of the children in the present study were given the Stanford-Binet test after the head injury. Three of these had been given the same test before the head injury. Thus Case IV (below) was tested twelve months before his head injury and received an I. Q. of 79. On the test given eight months after the accident the I. Q. was 74. Case XII (Appendix) was tested three years before his head injury and obtained an I. Q. of 97. When tested fourteen months after the accident his I. Q. was 97. Case V (below) was tested three years before his head injury and received an I. Q. of 97. On the test eighteen months after his accident the I. Q. was 99.

In these 3 cases the two tests, given before and after the head injury, were as close to each other as Stanford-Binet results can be expected to be when repeated on the same individual. Two of these 3 cases received severe head injuries,

and in all 3 cases a parent attempted to sue for damages. The following case is presented to illustrate this situation.

**Case IV.—Reason for Referral.**—C. G., a twelve-year-old white boy, in opportunity class, was referred in May, 1936, to the clinic six months after his accident. Ever since the accident he has been nervous, suffering from headaches, and his school work has become worse.

**Development.**—The eighth of 9 children. Birth and development were normal (according to the father). At eight and one-half years he had an appendectomy. Father says that up to the accident he was a happy, typical boy, doing well in school, playing well with other children. In contrast to this the school said that before the accident the patient had failed so much (at nine years he was in low third grade and doing only first and second grade work), they gave him a Binet test and put him in the opportunity class (for dull children) one year before the accident.

**Accident.**—At eleven and one-half years patient fell down a 14-foot embankment, onto concrete, injuring his leg and head. He was unconscious for two hours. When he came to, he vomited and was dizzy. He was taken to a physician's office. The father quotes the physician as saying that patient suffered from a "permanent nerve injury." Father is suing the owner of the property for \$15,000.

**Recent Behavior.**—Father claims that the accident affected the boy's mind (making him feeble-minded), and his nerves—he has headaches, gets "shaky spells" and bites his nails. Also patient has pains in his legs and his back. Father also claims that patient's spine has become crooked. Evidence from the school indicates that patient's school work has not become worse since the accident.

**Home Environment.**—The father is a rather dull man who never kept a job long. Three years ago he injured his head in an accident. He sued and was awarded \$1000 which has not been collected.

Since then he has been on relief on an occasional Federal job. The mother had little education. Was fourteen years old when she married. Bearing 9 children and 3 operations for gallbladder trouble have kept her ill a great deal. The oldest son was in an accident. The father sued and collected \$171. The second son has tuberculosis. The third son was in an accident at nine years which left him "mentally defective." The father sued and collected \$200. This boy finished the sixth grade at sixteen years. The father tried to get him into the school for the feeble-minded but the school refused to accept him.

**Examinations.—Psychologic.—School tests** (given twelve months before the accident).

Stanford-Binet: chronologic age, nine years eight months; mental age, seven years eight months; I. Q., 79. Tests ranged from six years to nine years.

At nine years eleven months he was given a reading test and scored at low first grade.

At ten years six months he was given arithmetic test and scored at low second grade.

**Clinic Test** (Given Eight Months After the Accident).—Stanford-Binet:

chronologic age, twelve years two months; mental age, nine years; I. Q., 74. Passed all of the nine-year tests and none of the ten-year (or above).

*Rating.*—Very dull intelligence.

Rogers Test of Personality Adjustment showed a high degree of maladjustment in every category but a particularly high "social maladjustment."

*Psychiatric.*—Patient said his mother worried most about his accident and fears he'll get in another. Father "just scolded me for being so careless." Father beats patient if he gets poor marks in school. Both parents threaten patient with reform school. Father fears patient will shoot someone. Mother makes the children behave by threatening them with the devil. Patient often dreams he is falling. Also dreams someone chops his mother's head off. Patient dislikes opportunity class and wants to go through college.

*Interpretation.*—Patient's present symptoms may partly be due to brain injury but they are aggravated by his mother's anxiety and his father's tendency to sue about all accidents. Patient's school achievement is handicapped by his dullness, but especially by his father's educational drive and his dislike for special education. This is based on father's need to prove that patient's dullness is due to an accident.

*Treatment.*—The psychiatrist interviewed the father urging him to drop the suit since the parents' continued anxiety was making patient more nervous. An attempt was made to get father to accept special education for patient, leading to trade training for semiskilled work. It was recently learned that the father did drop the suit and the patient has improved.

A similar situation is illustrated by Case XIV in the Appendix.

One case (V below) would not fit in any of the categories described above. This boy had a severe head injury while being treated at the clinic. Before the accident his behavior was somewhat similar to the children described above as showing "explosive tantrums." However, he improved under treatment and continued improving in spite of his accident. The report of this case follows:

*Case V.—Reason for Referral.*—G. G., a seven-year-old white boy, in low second grade, was referred in December, 1932, to the clinic, three years before his accident. He stole, was hyperactive, disobedient, destructive and unmanageable.

*Development.*—Third of 4 children. Birth and development were normal. Has always had nocturnal enuresis until seven years of age. Has always been nervous, hyperactive, mischievous and annoying. The school reported his behavior as "explosive." Patient is annoying in class and unpopular with children. Constant attention-getting behavior.

*Accident.*—(See below.)

*Home Environment.*—The mother was brought up in a miserable home. None of her children were wanted and she was unable to control them,

especially the boys. She was a religious fanatic. The *father* was always very serious and good in contrast to his father, who was a drunkard. He is a religious fanatic and is very intolerant of any misbehavior by his boys. They show the four traits he loathes the most—lying, stealing, cruelty and obscenity. He punishes them severely and adds that God will punish them too. Mother died when patient was six years old. After mother's death all 4 children were placed in boarding homes until father remarried two years later. *Patient* was in two boarding homes. Although he improved, the boarding mother felt he was so hopeless she asked that he be removed from her home. All the children went home four days after father remarried. The *stepmother* is also a religious fanatic who is very intolerant. Thus going to movies is a sin. She had a nervous breakdown prior to her marriage and was ill a year. She had no control over patient at all.

*Examinations.—Physical.*—Findings were essentially negative.

*Psychologic.*—(Tested three years before his accident.) Stanford-Binet: chronologic age, seven years three months; mental age, seven years; I. Q., 97. Tests ranged from five to nine years.

*Rating.*—Average intelligence.

Scores on three performance tests were average.

(Tested one and one-half years after the accident.) Stanford-Binet: chronologic age, eleven years eight months; mental age, eleven years seven months; I. Q., 99. Tests ranged from nine to sixteen years.

*Psychiatric.*—Patient shows many signs of feeling very insecure. He has been told that his swearing and stealing made his mother die. He describes his father and stepmother as very punishing and repressive and says he was happier in his foster home. He frequently mentions the things he does as sins. "God doesn't want children to go to the movies."

*Treatment.*—As both father and stepmother were unable to control patient, and as he was getting steadily worse in his behavior it was recommended that he be placed in a foster home, preferably in the country.

*Patient was placed* on a farm home at eight and one-half years of age (five months after his father remarried). The patient has been in that home for three years (1934 to 1937) and his behavior has improved steadily. He has made steady progress in school. At eleven years he is in the fifth grade and doing passing work. He has been brought to the city occasionally to visit his home and to be seen by the psychiatrist. After he was in this home one and one-half years he received his *head injury* (see below). The psychiatrist resisted attempts by the father to sue, to have a court trial and to have the boy brought home. Psychiatrist insisted on patient being sent back to the same foster home and no more attention be paid him than if he broke a leg. In the one and one-half years since the accident patient's progress has continued so that his stepmother said "The accident knocked the badness out of him."

*Accident*—At ten years, while in a foster home under clinic and agency treatment, patient was hit by a truck. Patient was unconscious a few minutes and later at the hospital became unconscious again. x-Ray showed a "circular fracture in the right temporal region. There is no evidence of depression." Patient was operated on the day of admission. A large bony plate was lifted

Extradural hemorrhage was found. Clots were removed, vessels ligated and bone flap replaced. A later x-ray showed the bone flap in good position and no evidence of depression. Patient made an excellent recovery and was discharged after three weeks.

### ETIOLOGY

In psychiatry the study of etiology is more complex than in most other branches of medicine. In 1936 the author wrote,<sup>22</sup> "Any attempt to study the etiology of behavior or personality traits is beset with seemingly insurmountable obstacles owing to the complexity of the problem. The variable and uncontrolled factors are so numerous that proof of a cause and effect relationship is nearly impossible. . . . A relatively recent, and widely accepted, theory has made the study of etiology even more confusing. This Theory of Multiple Etiology states that every behavior or personality trait is the result of many causal factors. This theory has two corollaries. One states that any trait, such as shyness, is caused by different sets of factors in different individuals. The other states that shyness in any individual is the result of many causal factors."

There is a strong tendency among medical men to resist this concept. They wish to simplify their thinking. Thus psychiatrists sometimes find it difficult to persuade general practitioners that a patient may have a serious organic condition (such as heart disease or tuberculosis) and a psychoneurosis at the same time. The tendency is to insist that the symptom is either due to organic or psychogenic factors, but not to both in the same individual.

Regarding head injuries, a few writers stress the organic factor of brain damage. Friedman<sup>9</sup> cautions us as follows: "On the basis of accumulating experience, we may say that, at least in some of the cases of 'traumatic neurosis,' definite organic changes that can be visualized in the encephalogram have been brought to light." Also Blau,<sup>5</sup> in discussing the 12 children with posttraumatic chronic behavior disorder, writes, "The principal interest in the post-traumatic behavior disorder in children lies in the fact that although it resembles a psychopathic personality reaction of psychogenic etiology, it is nevertheless definitely of organic origin and is probably caused by a localized lesion of the brain."

Some writers stress the factor of constitution or heredity. Thus Healy<sup>11</sup> writes, "Other possible causes are also nearly always in the background. Often we have gained evidence of a prior neuropathic constitution, or of some grave defect in heredity. Except in a case of arrested development, we can fairly say we have never been able to discern traumatism as the sole assignable factor."

Although some authors stress the functional or psychogenic aspects, most of them point out the necessity of considering both organic and functional factors in these cases. Thus Meyer<sup>19</sup> in 1904 wrote, "Looking over our cases etiologically, we cannot fail to be impressed by the concurrence of several etiological factors in the greater majority." Strauss and Savitsky<sup>23</sup> cite Babinski<sup>1</sup> as being one of the first to emphasize the frequency with which organic and functional disease can occur in the same patient. Strauss and Savitsky<sup>23</sup> agree that this concurrence exists. They write, "Such psychogenic superimposition is much more common than is usually admitted. . . . It is necessary for once to abandon the specious dichotomy, organic and psychogenic, in an approach to cases of head injury. In most cases there is a subtle interaction of psychic and organic factors. A case is not either organic or functional." Regarding etiology Strecker and Ebaugh<sup>24</sup> write, "The findings should lead to caution in referring these conditions to hypothetical molecular changes in the brain. We should prefer to think of the problem in terms of the total reactions of the individual child. A study of the child, the situation and the environment, and the reaction to this situation before and after the injury is therefore imperative." Kasanin<sup>17</sup> minimizes the specific effect of brain damage. He writes, "It seems to me that severe brain injury and encephalitis as such do not cause a specific reaction in the individual so far as his behavior patterns are concerned. It appears that any factor which causes a diffuse process in the central nervous system will interfere with the formation of proper inhibitory influences and will greatly hinder the complete integration of the individual's behavior."

Stressing functional factors, Kasanin<sup>17</sup> writes, "It is very frequent that the overzealous and anxious parents focus the attention of the child upon the injury and the clinical picture

then may be entirely due to functional factors." Barraclough<sup>2</sup> studied the behavior and personality of children following various illnesses, including head injury. He stresses the factor of emotional handling by parents. Bender,<sup>4</sup> in an article in which she describes a relationship between encephalitis and head traumas in children, and psychopathic personality, writes, "Of great interest is the fact that personality deviations as severe as any of these we have described may develop in a child who has had no birth injury, skull fracture or encephalitis but who has been deprived of the normal family-social life at the critical period in life, which is the preschool age, when his personality is maturing. As a result we find disturbances in the integration of the maturation patterns of the brain as serious as though the injury were a structural one. . . . Such a child is always emotionally infantile, always craving the love of the mother it never had and is insatiable in his demands for attention, grasping and clinging psychically. He is restless and has marked hyperkineses. His instability as he grows older will show criminal or psychotic episodes. Neurological deviations are usually absent but motility mannerisms may so closely resemble them that at times they are confusing to the examiner."

In the present series of cases a study was made of the functional, psychogenic or environmental factors that may have an etiological bearing. The results of this study are presented in Table 1.

The commonest finding, parental anxiety, is seen most frequently in mothers. It is a common observation that parents tend to blame a fall in infancy for difficulties their children show later. Parents need to project the origin of their child's maladjustment onto some cause, such as head injury, in order to protect themselves from being considered responsible. A certain amount of maternal anxiety is normal. It seems nearly always to be exaggerated when the injury is to the head. Thus a broken leg produces only a small fraction of the emotional response brought out by a fractured skull. The head represents a sort of magic zone, with a large number of superstitions regarding injury in that area. Similar clinical pictures are sometimes seen in children who have had birth injuries. Physicians have warned the mothers that the children would be

TABLE 1

PSYCHOGENIC AND SITUATIONAL ETIOLOGIC FACTORS (20 Cases)

Factor.	Mothers.	Fathers.	Total.	
	Number of cases.	Number of cases.	Number of cases.	Percent-age.
1. Parent shows extreme anxiety regarding patient.	15	2	16	80
2. Parent rejects patient.	12	8	15	75
3. Parent is extremely unstable or neurotic.	11	11	14	70
4. Home is broken.	..	..	7	35
5. Parent attempted to sue for damages.	..	..	7	35
6. Patient shows marked feeling of insecurity.	..	..	6	30
7. Parent puts a great deal of educational pressure on patient.	3	3	4	20

nervous. This has resulted in intensifying the mother's normal anxiety. The findings of the present study indicate that the child's behavior correlates more closely with the intensity of the parent's emotional response, and less closely with the severity of the injury.

The next most frequent factor is the rejection by one or both parents, most frequently the mother. The author reported a study of this factor in two papers.<sup>21, 22</sup> In the first paper<sup>21</sup> the author wrote, "The study shows that maternal rejection is primarily due to the mother's unhappy adjustment to marriage. This in turn is usually a result of immaturity and emotional instability on the part of one or both parents. These mothers express their rejection by undisguised forms of neglect and cruelty, by overprotection as a reaction to feelings of guilt, or by an inconsistency of handling, characterized by a mixture of these two methods. The children in turn, suffer from an unstable environment and inconsistent handling. Feeling more insecure than the average child, they are im-

pelled by the necessity of extracting from their parents and other adults expressions of being welcome or important. Thus they are peculiarly sensitive to attention. They derive a certain satisfaction from having their mothers upset about them and much of their specific behavior represents a discovery on their part of what their mothers fear the most. Finally, this study supports the conclusion that maternal rejection is an important factor underlying the insecurity which so often accompanies the clinical picture of emotional instability." In this respect the cases of the present study are somewhat similar in their clinical pictures to the cases of rejection studied. Thus in both studies there was a high per cent of broken homes (36 and 35 per cent), one or both parents are extremely unstable or neurotic (60 and 70 per cent) and the patients feel insecure. The main difference in the groups is the finding in the present study of head injury and the extreme emotional response of parents to this injury.

#### PROGNOSIS

Most writers are quite pessimistic regarding the prognosis of behavior disorders in children following head injury. Kasanin<sup>17</sup> concluded that the prognosis was poor, but not so poor as that seen in children following epidemic encephalitis. Healy *et al.*<sup>14</sup> feel that the prognosis for delinquents showing "traumatic constitution" is relatively poor. Strecker and Ebaugh<sup>24</sup> studied 30 children showing behavior changes following head injury. They state that 6 (20 per cent) are improving but the outlook for 24 (80 per cent) is discouraging. Beekman<sup>3</sup> studied 19 children showing behavior changes following head injury. He gives a more encouraging prognosis. He writes, "Ten children (52 per cent) recovered entirely, 6 (31 per cent) were much improved, but in 3 (16 per cent) no change was noted." He feels that there is a relation between the severity of the injury and the seriousness of the behavior disorder. The present study does not bear this out. Baraclough<sup>2</sup> also disagrees with Beekman. He writes, "The degree of severity of the initiating illness or accident bears no relation whatsoever to the behavior change for which it is blamed. Most trivial accidents and minor illnesses are frequently accepted as being responsible for symptoms that appear."

In the present study 4 cases (20 per cent) showed marked improvement and 9 cases (45 per cent) showed slight improvement under treatment. Four cases (20 per cent) showed no improvement and three (15 per cent) showed only temporary improvement. The relationship of these findings and treatment methods will be discussed later.

### TREATMENT

Regarding treatment, most authors agree on the value of a change of environment. In Healy's early study<sup>11</sup> he advocates a quiet rural life and stresses the avoidance of alcohol and overheating. In a more recent study Healy *et al.*<sup>14</sup> again advocate rural placement or "the steady regime of small semi-disciplinary schools." Regarding treatment Beekman<sup>3</sup> writes, "Care, isolation from emotional excitement and training quickly showed their effects on these children's behavior." Kasanin<sup>17</sup> writes, "It seems to me that in as much as any form of organic treatment is impossible in these cases, the only method of treatment is environmental change and psychotherapy." He feels that if usual methods fail, correctional institutions should be used for the training of the child and the protection of society.

Strecker and Ebaugh<sup>24</sup> discuss treatment thus, "Rest from physical and mental exertion, removal to a quiet, nonirritating environment, intensive study in mental hospitals, more individual consideration in school, special classes and vocational guidance, are all matters of importance in treatment. . . . During periods of mental excitement, we find that drugs are of little avail, but hydrotherapy is often helpful."

In the present study an attempt was made to correlate the treatment methods used with the results obtained. This is shown in Table 2. It will be seen from this that the best results were obtained by psychotherapy with the patient directly, and advice given to parents regarding methods of handling the child. In this advice the author urges parents to treat the child more as a normal child and to drop damage suits. The need to sue for damages affects the child indirectly by prolonging the emotional attitude of the parents. In the author's opinion the harm done by this attitude far outweighs the benefits derived by bringing suit for damages.

TABLE 2

## TREATMENT METHODS AND RESULTS (20 Cases)

Treatment methods.	Totals.	Results.				
		Marked improve- ment.	Slight improve- ment.	Tem- porary improve- ment.	No improve- ment.	Results unknown
		4	9	3	2	2
1. Psychotherapy of patient plus advice to parent.	5	3	2			
2. Advice to parent only.	3	...	3			
3. Psychotherapy of patient only.	1	...	1			
4. Tutoring of patient only.	2	...	2			
5. Psychotherapy of patient plus tutoring.	1	...	1			
6. Psychotherapy of patient recommended but not carried out.	2	...	...	...	2	
7. Placement in foster home.	1	1				
8. Placement in institution (short period).	3	...	...	3		
9. Placement in institution (long period)	1	...	...	...	...	1
10. Psychotherapy in home city recommended.	1	...	...	...	...	1

In some instances tutoring in specific subjects was beneficial to the child. Placement of the child in a well-run institution results in temporary improvement, but in each case the child resumed his former behavior difficulties soon after he returned home. The author feels that more prolonged treatment in a mental hospital equipped to care for children is indicated in many of these cases. Some of these children would profit by the hospital treatment designed for encephalitics and described by Bond and Appel.<sup>7</sup> They describe an experience similar to that seen in this study. They write, "Forty-six of forty-eight postencephalitic children improved while at the hospital." A follow-up study of a group sent home showed that over half made doubtful adjustments or became worse. On the other hand 45 per cent made good social adjustments. Most states lack facilities for the hospital treatment of children showing serious behavior disorders following encephalitis or head trauma.

## CONCLUSIONS

1. A study is presented of 20 children seen in a child guidance clinic who showed behavior or personality disturbances following head injury.

2. Half of the children suffered from severe head injury. In all of the cases where the injury was of a mild degree the parents blamed the injury for the disturbances shown.

3. The behavior and personality disturbances were classified, with some overlapping, as follows:

I. Children showing neurotic symptoms.....	10 cases
II. Children showing delinquent behavior .	5 cases
III. Children showing explosive tantrums . . . . .	4 cases
IV. Children showing mental retardation .	5 cases

4. The mental retardation was found to be more functional than actual. The children did poorly in school, but no deterioration could be detected by psychological tests.

5. Three cases are presented who were given the Stanford-Binet test before and after their head injury. In each case the results were nearly identical.

6. In studying etiology the necessity is stressed of considering organic and psychogenic factors as operating at the same time.

7. The effect of organic brain injury seems to be a diffuse increase of irritability with a general decrease of inhibitory functions. The effect of brain injury on behavior and personality is in no sense specific.

8. There is little correlation between the type of severity of the change in the child's behavior with the severity of the head injury.

9. There is a greater correlation between the behavior change and the emotional attitude of the parents toward the injury. These parental attitudes become important etiologic factors of a psychogenic or situational type.

10. The commonest situational factors were attitudes of extreme anxiety on the part of the parents and extremely unstable home situations. The parents were frequently unstable, neurotic and rejecting and the homes were frequently broken.

11. The prognosis is not so poor as some authors have described. In the present series 4 cases showed marked improve-

ment under treatment, 9 cases showed slight improvement, while the rest showed none or only temporary improvement.

12. The most effective therapy was found to be direct psychiatric treatment of the child combined with advice to parents regarding methods of handling the child. In this advice parents are urged to drop damage suits and to treat the patient more as a normal child.

13. Placement in institutions of a nondisciplinary type benefits some of these cases but the effects are temporary unless the placement can be arranged for a prolonged period and the child treated psychiatrically. Only a few states have children's wards in mental hospitals where the cases with severe behavior disturbances can be adequately treated.

#### APPENDIX

*Case VI.—Reason for Referral.*—H. N., a nine-year-old white boy, in second grade, was referred in November, 1933, to the clinic, four years after his accident, because of poor school progress since his accident. He has nocturnal and diurnal enuresis. "He can't learn. He forgets so easily."

*Development.*—First of 3 children. Birth full term, breech delivery with instruments. Never breast-fed as mother's milk was not suitable. Pneumonia at nine months. Talked at ten months. Walked at fourteen months. Mother said he has always been nervous and has always wet the bed.

*Accident.*—At five years ten months patient was hit by an auto. Was unconscious ten minutes, vomited, became drowsy, cried and trembled. Was semicomatose for some time and examined thus. Had many lacerations and contusions over the scalp. Eyes deviated to the left. Liver edge felt. Abdominal reflexes absent. Babinski and Oppenheim reflexes positive bilaterally. Right pupil more active than left. Pulse 114 to 102. Temperature around 100° F. for several days. Blood pressure, 100/50 to 118/80. x-Ray showed fracture of right clavicle and "questionable fracture of skull." No spinal fluid taken. Diagnosis: concussion of brain. Recovery uneventful and discharged in nine days.

*Recent Behavior.*—Patient is timid, afraid of the dark, bites his nails, and has nocturnal and diurnal enuresis. He only plays with younger children. He cannot stand being scolded. He always learned slowly and forgot easily. Repeated first grade and is repeating second grade.

*Home Environment.*—The father is a bus driver who didn't go far in school. The mother divorced him because he wouldn't support her. She remarried a man by whom she had two children. Mother thinks patient is like his father. She is an immature, nervous person who scolds and nags patient, but is fearful about his health.

*Examinations.*—Physical and neurologic examinations were negative except for an injected pharynx.

*Psychologic.*—Stanford-Binet: chronologic age, nine years seven months;

mental age, eight years four months; I. Q., 86. Tests ranged from seven to ten years. Rating: dull normal intelligence.

*Psychiatric.*—Patient said mother left father as he got drunk and used to beat mother. Patient sees father but if he comes near the house mother has him arrested. Mother worries a lot about his health and restricts his play for fear he'll get in trouble. His stepfather beats him a lot. Both parents favor his baby sister. Patient tells of the accident and adds that two years later a boy threw a stone and hit his head on the spot that was injured previously.

*Interpretation.*—Patient is immature in his emotional development and feels insecure. He has conflicts about his parents' separation and he is uncertain regarding his mother's love. His enuresis is partly due to this insecurity. Some of his present symptoms are due to his mother's anxiety regarding him and her exaggeration of the importance of the accident.

*Treatment.*—Patient and mother were asked to return to the clinic but did not return in the past three years.

**Case VII.—Reason for Referral.**—W. S., a thirteen-year-old white boy, in the seventh grade, was referred in November, 1933, to the clinic, thirteen months after his accident. He has been nervous and had headaches ever since his accident.

*Development.*—Second of 3 children. Birth and development normal. Was a happy, ordinary child until his accident. Repeated the fifth grade. Tonsils removed at three years. Has worn glasses since six years old.

*Accident.*—At twelve years of age patient was hit by an auto and received laceration of the shoulder and injury to his head. No skull fracture, or unconsciousness.

*Recent Behavior.*—Mother claims he has been nervous ever since his accident. He gets severe headaches and has periods of feeling weak and dizzy. These come on after reading, or after some unpleasant incident, as being scolded. Is upset by the least thing. Gets irritated at his mother, saying "Don't worry me. Leave me alone." Is afraid his father will harm him bodily.

*Home Environment.*—The mother divorced the patient's father when patient was four years old. She remarried. Three years ago mother had a "nervous breakdown." She seems very unstable. She fears the father will take patient away or harm him, so she frequently warns patient to avoid the father.

*Examinations*—Physical and neurologic examinations were essentially negative.

*Psychologic*—Stanford-Binet: chronologic age, thirteen years four months; mental age, fourteen years three months; I. Q., 107. Tests ranged from twelve to eighteen years.

*Rating.*—High average intelligence.

*Psychiatric*—Patient seems like a weakling and very dependent on his mother. Says he hates his father as he was mean to mother. Both he and mother are nervous. She is always after him not to play rough or he'll get hurt. He is especially jealous of his half-brother. Describes quarrels and disagreements regarding discipline between his parents.

*Interpretation.*—Patient's nervousness is largely a reaction to his mother's neurotic behavior and her anxiety that he was seriously injured in the accident. Patient sides with mother in his thinking and he also feels the accident made him nervous. He also sides with mother against the father and shows a little resentment at mother for remarrying and having more children. Patient is developing neurotic tendencies.

*Treatment.*—Psychiatric treatment at the clinic was offered but neither patient nor his mother has returned in three years.

**Case VIII.**—*Reason for Referral.*—N. K., a ten-year-old white boy, in low fifth grade, was referred in September, 1936, to the clinic, seven years after his accident. He has stuttered ever since his head injury.

*Development.*—Third of 4 children. Birth normal, breast-fed nine months. Development normal. No serious illnesses, food fads or nervous habits. Has a good disposition and is popular with children. In school repeated high fourth grade. Is slow in his work.

*Accident.*—When three and one-half years of age patient was hit on the head by a golf club. His head was severely cut and several stitches were necessary. Patient's stuttering started immediately after this. The physician who attended him said it was due to the fright and shock and that he would outgrow it.

*Recent Behavior.*—Patient has stuttered ever since his head injury. He does it most when he is excited. He is very much ashamed of this handicap, especially as it interferes with school recitations. He is afraid of doctors and hospitals. On the whole he has a pleasant personality and gets on well with children and adults.

*Home Environment.*—The father is well educated and kindly but not able to support the family very well. The mother married at sixteen years and feels she has missed the good times her friends have had. She is a little rebellious at her husband's old-fashioned ideas, and her lack of recreational opportunities. She is quite worried about patient. Both parents put quite a bit of educational pressure on their children.

*Examinations.—Psychologic.*—At nine years ten months of age patient was given the National Intelligence (group) Test and received an I. Q. of 105.

Stanford-Binet: chronologic age, ten years eight months; mental age, nine years; I. Q., 84. Tests ranged from eight to ten years.

*Rating.*—Dull intelligence.

On a series of 10 performance (manual) tests patient obtained an average mental age of nine years. Patient is right-handed.

*Retest* after seven months of treatment.

Stanford-Binet: chronologic age, eleven years three months; mental age, ten years one month; I. Q., 89. Tests ranged from eight to twelve years.

*Rating.*—Dull normal intelligence.

On a series of 12 performance tests patient obtained an average mental age of ten years.

*Psychiatric.*—Patient describes his father as being very punishing, especially if patient gets poor marks in school. Patient's ambitions, to be a doctor or lawyer, are definitely beyond his ability. Patient shows extreme jealousy of

his fifteen-year-old brother. They fight every day. "I half kill him." In the interview patient stuttered only when the topic upset him.

*Interpretation.*—Patient's stuttering seems to be a neurotic trait, started by the mother's marked anxiety at the time of his accident. It continued as a habit because by it he derives the infantile satisfaction of having his mother continue to show anxiety and be protective of him.

*Treatment.*—He was seen for 7 psychiatric interviews and has had weekly tutoring and remedial exercises by the psychologist for a period of seven months. Patient has shown definite and steady improvement.

*Case IX.—Reason for Referral.*—W. B., an eleven-year-old white boy, in low fifth grade, was referred in January, 1936, to the clinic, five years after his accident. He fights a lot, bites his nails, sucks his thumb, masturbates, wets his bed, walks in his sleep and daydreams a lot.

*Development.*—Second of 5 children. Birth and development were normal. Was bottle-fed until eighteen months of age. Usual childhood diseases. At three years of age was severely ill with pneumonia. Has had growing pains and joint pains, claims he doesn't hear well.

*Accident.*—When six years old patient was hit by an auto. He was unconscious and came to in the hospital. x-Ray showed a linear fracture in left parietal region. No depression. Recovery uneventful and patient was discharged after nine days.

*Recent Behavior.*—Patient is irritable, fighting frequently with his younger brother. If scolded or whipped he becomes sullen. He tends to be seclusive. He is repeating his grade in school for the first time. See above for list of his problems. He has always had nocturnal enuresis.

*Home Environment.*—The father was brought up strictly. He is a dull, ignorant man who drinks a lot, quarrels with his wife, neglects his children and shows serious neurotic symptoms. The mother was brought up in an extremely unstable home (her mother being psychotic). At fifteen years of age she was sent to a girl's reformatory for one year. She has been very promiscuous ever since she was sixteen years old. She spends only a few hours a week at home. She is a notorious drunkard and fighter. She was sentenced to a year in jail. The home was broken up and the children placed in foster homes.

*Examinations.—Physical.*—Patient is undernourished. Tonsils moderately enlarged and infected. Anterior cervical nodes large and tender. Slight tenderness of knee and elbow joints. Dental caries. Gait is springy, favoring left side. Carries left arm semiflexed. Reflexes active but equal. No pathologic reflexes. Tonsillectomy and dental care were recommended.

*Psychologic*—When patient was ten years old he was given the Illinois Intelligence (group) Test and was given an I. Q. of 116.

Stanford-Binet chronologic age, eleven years one month; mental age, ten years ten months, I. Q., 98. Tests ranged from ten to fourteen years.

*Rating.*—Average intelligence

On a series of 9 performance (manual) tests his average mental age was nine and one-half years. Goodenough drawing test: score, 49

This is equivalent to a mental age of nearly fifteen years. His drawing shows some talent.

*Psychiatric.*—Patient describes his mother's neglect but tries to defend her. He describes his father as being very strict and punishing severely. He feels insecure and unhappy. He was in uncle's home a while and hated it. He dislikes his present boarding home. He shows rather strong ties to his family. On the whole he has a repressed, colorless personality.

*Interpretation.*—Patient's head injury has little to do with his present behavior. This is largely affected by his extremely unstable home setting.

*Treatment.*—It was recommended that he be placed in another foster home. This was done and in ten months practically all of his symptoms have disappeared, including his enuresis.

**Case X.—Reason for Referral.**—H. B., a seventeen-year-old white boy, was referred in June, 1935, to the clinic, seven years after his accident. He has run away from home several times.

*Development.*—Second of 3 children. Was one and one-half years old when his mother died and was raised by his paternal grandmother. Birth, health and development were normal except for some retardation.

*Accident.*—At ten years of age patient was struck by an auto. He was unconscious for two days and was in the hospital four months. (The hospital never replied to our letter asking for a report.) Since then patient has been hit on the head twice and was unconscious both times.

*Recent Behavior.*—Since his accident patient became disobedient in school and was taken to Juvenile Court because of truancy. He also began running away from home and did this frequently. Grandmother blames this on the head injury. Patient quit school at sixteen years in the seventh grade.

*Home Environment.*—Mother died (soon after the birth of her third child) when patient was one and one-half years old. Was raised by his paternal grandmother who was very strict and punished patient a lot. Patient was his father's favorite and was treated very leniently by him. Father and grandmother frequently quarreled regarding patient's discipline.

*Examinations.—Psychologic.*—Stanford-Binet: chronologic age, seventeen years; mental age, eleven years six months; I. Q., 72. Range nine to sixteen years.

*Rating.*—Very dull intelligence.

A series of 12 performance (manual) tests gave him an average mental age of fourteen years.

*Psychiatric.*—Patient describes himself as being spoiled by his father. He describes his grandmother as being very strict, but since his accident she has feared he will be a criminal. Patient has many feelings of inferiority which were intensified by his accident. Thus his younger brother passed him in school since the accident. Also since his accident he became afraid of playing baseball. He began going with a tough gang of boys, trying hard to win their approval.

He seems somewhat unstable and will lose jobs but the general prognosis seems fair in the sense that he will be able most of the time to support himself and will not be markedly antisocial.

*Treatment.*—It was recommended that he be treated by the traveling psychiatric clinic that visits his home town. If adjustment fails he might either be sent to a C. C. C. camp or the State Industrial School for a period.

*Case XI.—Reason for Referral.*—L. B., a twelve-year-old colored boy, in third grade, was referred in March, 1936, to the clinic, six years after his accident. He runs away from home, steals and has "spells."

*Development.*—Third of 7 children. Birth and development normal. Tonsillectomy and adenectomy at eight years of age.

*Accident.*—At seven years patient was hit by a street car and dragged some distance, receiving scalp lacerations. The mother collected \$150 plus medical care as compensation. (The hospital never replied to our letter asking for a report.)

*Recent Behavior.*—A year after the accident patient started running away from home and did so almost continuously to the present. He has been picked up by the police and brought to Juvenile Court innumerable times. Occasionally he steals. He usually travels alone and tells people how badly treated he is at home. He was sent by the court to three different institutions. He was sent twice to the State Industrial School for Colored Boys but ran away so often they refused to accept him again. His school attendance has been extremely irregular. He recently complains of headaches and spitting up of blood. His mother says that in the past month he has had two "spells" of fainting. The mother blames all of patient's trouble on the accident.

*Home Environment.*—The mother has had 7 children by 3 men. Only 1 of her children is legitimate. The patient is illegitimate. The mother never lived with the father although she bore him 4 children. The mother does domestic work and is away all day and has no control over her children. Of her children the patient is the most uncontrollable. She has had treatment for syphilis.

*Examinations.—Physical.*—Scalp scar over left frontal and temporal region. Mucous membranes pale. Small, shotty glands palpable in the neck. Chest examination negative. Right pupil larger than the left. Both react normally.

x-Ray of chest is negative.

Blood Kolmer test is negative.

*Psychologic.*—Stanford-Binet: chronologic age, twelve years nine months; mental age, seven years two months; I. Q., 56. Tests ranged from six to nine years.

*Rating.*—Feeble-minded.

*Psychiatric.*—Patient was extremely resistive. Sat staring at the floor with expressionless face and answered all questions in monosyllables. His usual answer to everything was "Nothin'."

*Treatment.*—It was recommended that he be placed in the State Industrial School for Colored Boys until he could be transferred to the new school for colored feeble-minded which had not yet been opened.

*Case XII.—Reason for Referral.*—A. I., a ten-year-old white boy, in low fourth grade, was referred in January, 1933, to the Cleveland Clinic, fourteen

months after his accident. Ever since his accident he has had violent temper outbursts, fighting and throwing anything he can reach.

*Development.*—Sixth of 9 children. Mother was very ill in pregnancy, having two severe hemorrhages. Mother nearly died at birth, which was cesarean. She had to have a transfusion. Patient was bottle-fed as mother had no milk. Patient had diphtheria at sixteen months of age. Development was normal, and patient was healthy until his accident.

*Accident.*—When nine years old patient was hit by an auto and received scalp lacerations. His left leg was broken at the hip. His hip was operated on four times, and he was in a cast, then on crutches and finally a brace. The mother is very emotional about the accident. She wants the clinic to help her collect damages and says she is sure patient's mind was affected.

*Recent Behavior.*—Patient's personality changed since the accident. He has violent, explosive temper outbursts in which he fights his brothers. Mother fears he will hurt someone. He has had none of these outbursts at school. At home he also shows marked food fads. Says, "I won't eat even if you kill me."

*Home Environment.*—The father is illiterate. He is very irritable and frequently fights with mother. He is being treated for syphilis. He has been in 3 accidents and tried unsuccessfully to sue each time. The mother is twelve years younger than father. She has been so unhappy in her marriage she is very resentful toward her mother who arranged it. She is very emotional especially when talking about patient's accident and behavior.

*Examinations.—Physical.*—Undernourished. The rest of the examination was essentially negative. Tuberculin test negative.

*Psychologic.*—Three years before the accident patient was given the Stanford-Binet: chronologic age, six years; mental age, five years ten months; I. Q., 97.

Fourteen months after the accident he was given the Stanford-Binet: chronologic age, ten years; mental age, nine years eight months; I. Q., 97.

*Rating.*—Average intelligence.

*Psychiatric.*—The patient describes his mother as losing her temper with patient but also as worrying too much about him. He admits liking this in some ways but still feels it is too much. His accident looms large in that he speaks of it several times spontaneously. Some of his attitudes and behavior are quite infantile. Fortunately he is very fond of his teacher and likes school.

*Treatment* was directed more at trying to lessen the mother's anxiety and emotional tension regarding patient. This was carried on two months (when the clinic closed) and was moderately successful.

*Case XIII.—Reason for Referral.*—C. S., an eight-year-old white boy, in low second grade, was referred September, 1934, to the clinic, five months after his accident. He is nervous, has headaches and is failing in school.

*Development.*—Third of 4 children. Birth and development were normal. Breast-fed ten days. Was on a bottle for two years. At three years he had scarlet fever and the family physician said he would have "weak kidneys." At five years of age patient was in an auto accident in which he was not

injured but a girl sitting beside him was decapitated. Patient was very nervous for several weeks, trembling and showing choreiform movements.

*Accident.*—See above for accident at five years.

At seven years of age patient was knocked down by a taxi and the right clavicle was fractured. No unconsciousness or evidence of head injury. Father collected damages out of court. Immediately after this accident patient became nervous, trembling and choreic, as with the previous accident.

*Recent Behavior.*—Ever since his first accident he has shown frequent and severe displays of temper, screams, throws things and has attacked his parents and his younger brother with a knife. He only plays with younger children and he is cruel to them. At school he is very troublesome, is punished a great deal and is failing. He is afraid to go to bed without a light. He has a poor appetite. He has frequent nosebleeds and headaches. He is extremely restless and hyperactive. His mother blames all these symptoms on the accident. She is sure his brain was injured and that he is losing his mind.

*Home Environment.*—The father has been ill with diabetes and tuberculosis and has been a poor provider. He drinks, stays out late at night and is mean and ugly to his wife. He shows no interest in the children and is especially irritated by patient. He calls patient unprintable names, hates to see him around and frequently threatens to have him "put away." The mother was sixteen years old when she was married and has been sorry ever since, he is so mean. She shows mixed feelings and behavior toward patient. She has been too lenient, giving in when he has a tantrum and being protective when father is mean to him. On the other hand patient gets on her nerves so that she can't stand him any longer. She becomes very sarcastic about him, scolds a lot and insists that he has to be placed somewhere. She fears patient will be like his father, get tuberculosis or lose his mind. The family lived with the maternal grandmother who also protected patient. He would run to her whenever his parents punished him.

*Examinations.*—*Physical.*—Patient has had many careful physical and neurologic examinations and no basis has been discovered for his headaches and nosebleeds. Tonsils were enlarged and were removed, eyes were examined carefully and findings were negative. At mother's insistence he was examined in the tuberculosis clinic and findings including tuberculin were negative.

*Psychologic.*—Stanford-Binet: chronologic age, eight years four months; I. Q., 84. Tests ranged from six to eight years.

*Rating.*—Dull normal intelligence.

Rogers Test of Personality Adjustment showed a high degree of maladjustment in every category but "daydreaming" which was low. The "social" and "family" maladjustments were especially marked.

Furfey Test for Emotional Development gave a Development Quotient of 88.

*Psychiatric*—Patient describes his mother as being overly anxious about his health and school work, "She doesn't want me to get killed. She wants me to take all the schools." He describes his father as being severe and openly rejecting. "He doesn't care about us. He says he's going to put us away." Patient is most upset by his mother's mixed behavior. He shows a definite

anxiety reaction regarding his accidents, and this has been intensified by his mother's concern.

*Treatment.*—Patient was placed in a children's convalescent school for five months. During this period he showed marked improvement physically and mentally. This improvement only lasted a few weeks after his return home. Treatment at the clinic was attempted, but the mother did not cooperate, insisting she only wanted placement. Patient was referred to a child-placing agency for placement in a foster home.

*Case XIV.—Reason for Referral.*—H. C., a nine-year-old white boy, in opportunity class, was referred in March, 1935, to the clinic, three years after his accident. He seems unable to learn to read.

*Development.*—Youngest of 3 children. Mother was very ill during the pregnancy. While mother was pregnant patient's four-year-old brother was kicked in the head by a mule and was unconscious some time. Mother then felt no "life" and thought patient had died. Birth was difficult as the baby was large. Breast-fed only two months as mother's milk was poor in quality. When cutting teeth he had convulsions. At two and one-half years he had a mild case of chickenpox followed by pneumonia, at which time he was delirious during the fever. At six years he cut his toe on a bicycle and it had to be amputated. After returning from the hospital he had occasional nocturnal and diurnal enuresis.

*Accident.*—At six years of age (six months after returning from the hospital) patient fell off a truck, cut his head and became unconscious. A private physician sewed him up and sent him home. He soon vomited and became unconscious again. He was taken to a hospital and diagnosed cerebral concussion. Two x-rays were negative for fracture of skull. Physical examination at the time was negative except for lacerations of the scalp, supra-orbitally, and semiunconsciousness. Spinal fluid was not examined. Recovery uneventful and discharged in six days.

*Recent Behavior.*—Patient shows hardly any signs of nervousness. He is pleasant, obedient and gets along well with other children. His main difficulty is his inability to learn to read. The father blames this difficulty on patient's head injury. Patient is very sensitive about his disability as children taunt him about it. Teachers say he is dull and when eight years old he was placed in the opportunity class.

*Home Environment.*—The father is a very nervous, high-strung, quick-tempered man who had a nervous breakdown (when patient was born and his brother was injured in the head) and he was incapacitated for four years. He frequently attempted suicide. The mother had an unhappy life as a child (broken home) and seems overwhelmed by her present home. She has been ill and weak since the birth of her first child and her husband has been incapable of supporting the family since his breakdown.

*Examinations.—Psychologic.*—At six years Detroit Group Test, I. Q., 96. Stanford-Binet: chronologic age, seven years four months; mental age, six years two months; I. Q., 84. Tests ranged from four to eight years. Stanford-Binet: chronologic age, nine years two months; mental age, eight years four months; I. Q., 91. Tests ranged from five to ten years.

At nine and one-half years, Metropolitan Reading Test, 1.7 grade.

At nine and one-half years, Metropolitan Arithmetic Test, 2.3 grade.

Dull normal intelligence rating.

Average ability on a series of performance tests.

On a series of tests for specific reading disability (Gates and Betts) he showed some tendency to reversal of letters, very poor phonetic ability and visual memory. His vision and acuity of hearing were normal and there was no eye muscle imbalance.

*Psychiatric.*—Patient showed a slight speech defect resembling a stutter. He is showing a few neurotic tendencies. He describes his mother as being markedly overanxious about his health and about his reading. He is somewhat afraid of his father. Both parents say he must be "dumb."

*Treatment.*—Patient was referred to a teacher who specialized in tutoring children with reading disability. The last report indicated that he had made marked improvement in his reading and was much happier.

### ACUTE EMPYEMA IN CHILDREN: DURATION OF ILLNESS PRIOR TO TREATMENT A FACTOR IN MORTALITY RATE

THE modern conception of the basic principles in the management of pleural empyema was established by the report of the Empyema Commission<sup>1</sup> of the United States Army in 1918. This work has stimulated considerable interest during the past twenty years in the creation of better methods of treatment. The concentration of thought in many instances has been centered upon various methods of technic which are a revival of the principles of suction, siphonage or valvular action.

Many authors have claimed that their results are primarily or entirely due to some particular method of operation. A close scrutiny of the many statistical reports bare conflicting evidence and leave one in a quandary as to which is the best operative procedure. It is to be admitted that variable percentages in the reports of death rates may be influenced by the type and virulence of the infection, or by monthly and seasonal variations. These factors will affect mortality rates regardless of the type of treatment.

The object of this report is to stress with particular emphasis a point which has heretofore received little mention. The particular point for discussion is: *the duration of illness prior to treatment as a factor in empyema complications as well as a factor to be considered in the deduction of mortality rates irrespective of the type of operative procedure.* The

duration of illness has considerable bearing on the development of complications, from which, in most instances, death must be attributed. Patients rarely die from empyema per se. Death may be due to septicemia, meningitis, brain abscess, pericarditis, lung abscess, liver abscess or peritonitis. One frequent complication not to be overlooked is postoperative pneumonia in the contralateral lung.

Our information is based on a study of 103 cases of acute empyema in children under thirteen years of age who were

Fig. 95.—This chart represents a study of the duration of illness, in weeks, prior to admission. The death and recovery cases are bracketed in separate columns. The smaller figures indicate the number of cases for the particular ages while the larger figures represent the total numbers in each square. Note the heavy line of demarcation between the third and fourth weeks in duration of illness. Twelve deaths occurred in the younger children who were ill more than three weeks prior to admission and treatment.

treated at the University Hospital from 1924 to 1934. The usual statistical findings in this group parallel those of similar reports found in the general hospital series.

The duration of illness prior to treatment was determined conclusively in 93 of the 103 cases. Twelve of the 16 deaths occurred in patients who had been ill more than three weeks. In the group of recoveries, 70 cases were ill three weeks or less, while 7 cases had been ill more than three weeks prior to receiving treatment. A sharp line of demarcation between the

fatal and the recovering cases fell between three and four weeks from the onset of the initial illness (Fig. 95).

It is a striking fact that no death occurred in the 44 children who were between six and twelve years of age (Fig. 96). The cause of death in 14 cases was proved by necropsy to be one or more of the complications mentioned above. Why did these deaths occur? With this point in mind the question was studied with respect to the type of infection and the duration of illness. Most of the deaths occurred irrespective of the type of infection in those cases who had been ill

Fig. 96.—The solid black columns represent the total number of cases of empyema for each year of age. The hatched columns indicate the number of deaths at the various ages. It is to be noted that there were no deaths between the ages of six and twelve years.

more than three weeks and many recoveries were found in the group who had been ill three weeks or less (Fig. 97).

It is reasonable to suspect that the delay in receiving treatment is due to the late diagnosis of pneumonia and empyema in the very young children. Complications are more apt to follow as a result of this delay. Therefore, higher mortality rates are to be expected. The treatment in some of this series of cases consisted of aspiration alone; in others, aspiration combined with open and closed methods of drainage with and without rib resection was done. The results are not attribut-

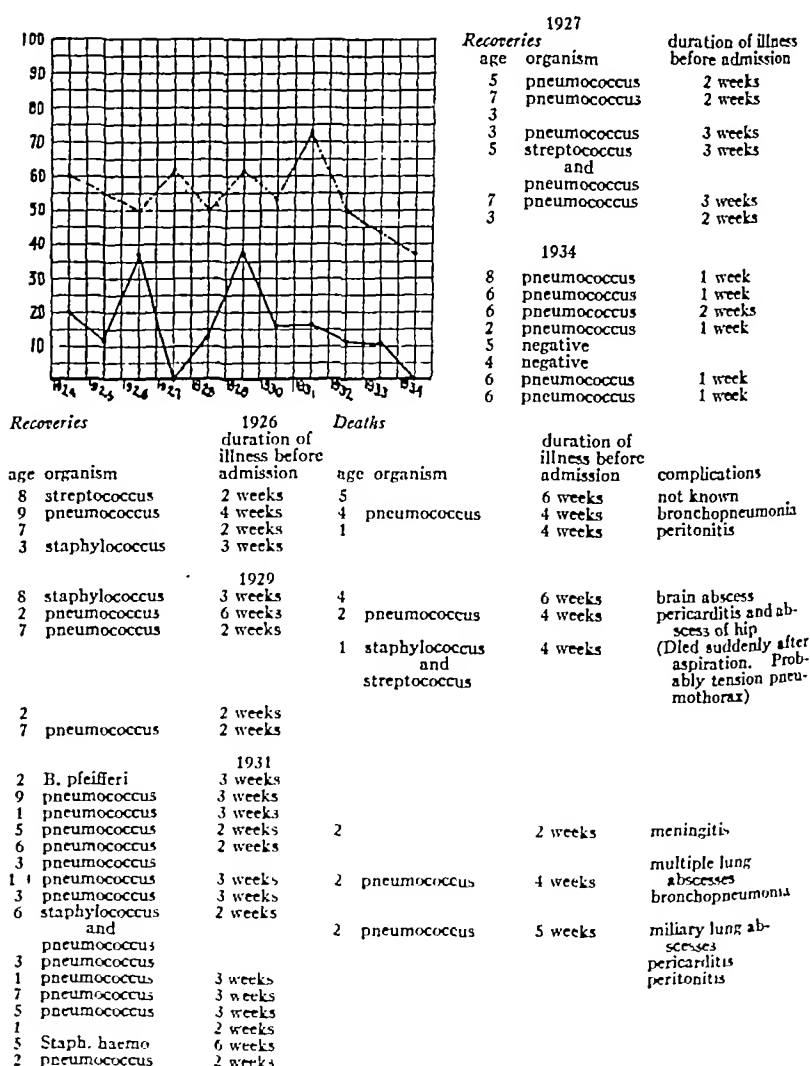

Fig. 97.—The solid curve in the graph shows the mortality rate per year in the 103 cases of empyema. The dotted curve represents the percentage of cases (five years of age or less) for each year. It is to be noted that the variable mortality rates for different years are not due entirely to the fact that most cases were in the very young age group. The high percentage of younger children in 1931 shows a comparatively low mortality rate. The mortality rates for 1926 and 1929 are tabulated with the ages, recoveries, duration of illness and type of infection. The duration of illness is an important contributing factor in these years of higher death rates. There are no deaths in 1927 and 1934. Note the duration of illness before admission, in the tabulated cases for these two years.

able to any one particular method of treatment. In these 103 cases there was not a single fatality among the group that developed empyema while being treated in the hospital.

### CONCLUSIONS

Any child suffering from suspected pneumonia, particularly those under six years of age, who show little or no improvement after ten days from the onset of illness, should have an x-ray examination of the chest. It is an ordinary precaution. Early recognition with proper treatment will greatly reduce the mortality in empyema.

It is not to be construed that the plea for early diagnosis is also an appeal for immediate operation after the diagnosis has been made. The individual factors in each individual case, such as the type and virulence of infection, the general condition of the patient, the consistency of the pus and the location and character of the empyema, should be some of the determining factors in selecting the time and plan of treatment.

The duration of illness prior to treatment may be a helpful index in the prognostication of complications and mortality rates.

## CLINIC OF DR. J. EDMUND BRADLEY

UNIVERSITY OF MARYLAND HOSPITAL

---

### DIAGNOSIS OF THE CAUSES OF LOW-GRADE ABDOMINAL PAIN IN CHILDREN

VAGUE recurring abdominal pain is a common complaint in children. It is a complaint that most frequently is uttered in the age group of three to ten years.

The pain presents no definite characteristics, with the exception of its almost constant localization to the umbilicus.

The causes of the condition are manifold, ranging from local disturbances to those far remote from the abdomen. The nature of the disturbances may be serious or comparatively trivial. Because of the numerous etiologic factors involved, and their associated variable nature, it behooves the physician to definitely arrive at a diagnosis.

To reach a diagnosis is frequently a complex problem as the complete absence of any pathognomonic subjective or objective findings is notable in this complaint. Therefore, confronted with the condition the only premise that can be advocated is—be thorough!

The citation of cases, exemplifying confirmation of the above statement, is probably the most satisfactory manner of illustrating diagnostic procedures.

Case I.—A colored boy, aged four years, was admitted to the University of Maryland Hospital with the complaint of vague, recurrent umbilical pain of several months' duration. Vomiting had been present for the past two days. The patient had had a similar attack one month prior to admission; at which time a diagnosis of "acidosis" was made.

The diagnosis of the condition in this youngster would have remained obscure, but for our routine inquiry as to the history of paint eating. Such a history was obtained and

substantiated by the presence of a lead line in roentgen-ray examination of the long bones. While lead poisoning is more common in infants, it is seen in older children. We strongly feel, however, that the diagnosis will seldom be made short of the encephalitic stage, unless routine inquiry is made in history taking. Peripheral neuritis, lead line and other adult features are usually absent in children. Yet the diagnosis can easily be confirmed or excluded by demonstration of the typical lead line in the long bones. This case is an excellent example of the importance of thorough history taking.

**Case II.**—A white boy, aged six years, was seen complaining of umbilical pain at recurring intervals for the past six months. There had been a concomitant anorexia, slight loss of weight and some lassitude. The history was strongly suggestive of tuberculosis: yet contact was denied. On examination definite nodular masses could be palpated in the region of the cecum. The Mantoux test in a dilution of 1:1000 was strongly positive. A flat plate of the abdomen revealed the presence of calcified glands.

The mesenteric glands are frequently the site of tuberculous infection. As a rule they give rise to very vague and unreliable symptoms and physical signs. When pain is present it is chiefly attributable to acute glandular inflammation, periaadenitic edema and local peritonitis of the adjacent serosa. The location is usually umbilical or lower right quadrant. The routine use of tuberculin testing, as a diagnostic aid in conditions of vague abdominal pain, is unreservedly urged, for the tuberculin reaction is of great significance when negative in that it provides very dependable evidence against the presence of tuberculosis. The diagnostic usefulness of roentgenography is almost exclusively limited to the demonstration of the old calcified stage of the disease.

**Case III.**—A white boy, aged ten years, was seen with the complaint of umbilical pain, usually following the ingestion of food. The complaint had been present since the age of three years. The pain was described as cramp-like and frequently associated with vomiting. The past history elicited the information that the child had vomited frequently as an infant and was termed a "feeding problem." As to the family, the patient was the lone child of parents who were lone children of their respective families. When examined the child presented a picture of combined malnutrition and nervous fatigue. Naturally there was a very strong tendency to class this patient as a behavior problem. But, because of the long duration of the complaint, he was subjected to a complete clinical investigation. A gastro-intestinal x-ray revealed

a definitely delayed emptying time of the stomach, which apparently was due to some obstruction below the duodenum. Operation was advised and peritoneal bands of adhesions were released.

The frequency of similar conditions is undoubtedly difficult to determine, as children suffering from peritoneal bands causing chronic manifestations present so many signs of nervousness that they are almost invariably classed as "the behavior child." Their pain varies from a feeling of heaviness to attacks of severe colic. Vomiting is outstanding, usually coming on after eating. In some cases the vomitus may contain food which has been ingested some hours before.

Case IV.—A white girl, aged nine years, was admitted to the hospital with the complaint of recurring umbilical pain for the past four years. There were associated symptoms of anorexia, failure to gain weight, fatigue, occasional nausea and car sickness. In the family history it was noted that the patient was the younger of 2 children and that there was a difference of eight years in their ages. On examination, the patient was of the asthenic type: the color was sallow; a marked lordosis was present, the scapulae were winged and the abdomen was prominent. A combination of findings which constitute a picture of nervous fatigue—a very extensive investigation was productive of entirely negative results.

This patient falls into an untermed group. Members of this group are felt by Cameron to manifest a definite ketonemia, though confirmation of this hypothesis is lacking. The abdominal pain is probably due to ptosis. However, these children when placed on a high carbohydrate, low fat diet plus adequate rest and systematic exercise for the correction of the postural defects and the hypotonia do surprisingly well. The diagnosis at the present time can only be made by exclusion.

Case V.—A white girl, aged seven years, was seen complaining of pain in the lower right quadrant, occurring at varying intervals during the past two years. The attacks were usually associated with some vomiting. Seen at the time of the attacks nothing of significance could be determined. The family history was of especial interest. The mother had been classed definitely neurotic, because for the past three years she would arise in the morning and have a bout of vomiting, complaining of severe abdominal pain. About six months after the onset of the mother's dilemma, the patient's brother, aged fifteen years, began to have the same symptoms. All of the family had been accorded a very complete investigation by their physician, with negative results.

It was felt that this patient should be accorded a laparotomy. The reason being that the appendix might be the offender because of the localization, the

vomiting and persistence. Neuroticism was strongly suggested and considered the most probable cause. Yet, at operation an appendix which had been the seat of repeated infections was removed.

Chronic appendicitis is the condition immediately suspected whenever abdominal pain is present. The diagnosis rests entirely on seeing the patient in an attack. Rectal examination gives a great deal of information in these patients and should never be neglected. The value of roentgenograms is subject to some difference of opinion, but they often give quite valuable information.

**Case VI.**—A white boy, aged eleven years, was seen with the complaint of recurrent attacks of abdominal pain. The pain was described as appearing in the lower right quadrant. There was nothing further of interest in the personal history. The family physician volunteered the information that during the attacks there was elicitable tenderness over the lower right quadrant, with no spasticity or rigidity, and rectal examinations had been negative. The family history gave a definite statement as to the presence of hives and asthma in various other members. Following this lead it was elicited that the boy intensely disliked eggs, but the parents did not think that the condition showed any tendency to be related to the intake of this particular food.

It was felt that with the strong allergic history in the family that the abdominal symptoms might be on an allergic basis, so it was suggested that eggs be fed the patient and the reaction, if any, noted. The advice was followed and the ingestion of eggs on the first occasion provoked a bout of abdominal pain. Their use on a second occasion was followed both by pain and an urticarial rash.

The history of allergy in the family should always make one suspicious that the abdominal pain symptom-complex might be due to hypersensitiveness. Certain food dislikes should not be overlooked, for these when forced may produce abdominal pain with definite allergic manifestation. Eosinophilia is very helpful and is probably present in a great number of these cases. The leukopenic index may be of assistance, but we unfortunately have had no experience with it. Cutaneous tests have not been helpful. The opinion has been expressed to explain this latter feature, that in gastro-intestinal allergic conditions the clinical reactions of the allergens are of the cumulative type.

#### DISCUSSION

A small group of patients illustrating a few of the causes of low-grade abdominal pain, and the diagnostic procedures

utilized in arriving at the cause have been presented. Obviously the list is not complete, as the literature contains numerous articles on this subject.

The difficulty of making a diagnosis in these conditions is readily seen. Thoroughness is the only reliable agent that the physician possesses.

In reaching a diagnosis a complete and exhaustive history and physical examination are essential. In taking the history the daily habits of the child, his diet, and his emotional life need investigation. The importance of psychic factors in the production of abdominal pain should however be taken with a grain of salt. Careful inquiry as to any history of allergy in the family should be made. Food idiosyncracies should receive their full attention.

The physical examination should be very thorough. That sinusitis and allied respiratory infections may be responsible for the complaint, through their production of adenitis, should be remembered. Rectal examination, as a routine procedure, should not be forgotten. It has been said that the difference between the practitioner and the surgical consultant is that the surgeon makes a rectal examination. More attention should be given to the importance of blood pressure determinations in children, as elevations may lead to the detection of heavy metal poisoning, adrenal tumors, kidney tumors, etc., conditions which while rare may have as the initial complaint abdominal pain. We recently saw a case of an adrenal neuroblastoma in a boy of six years, with a blood pressure of 160/130, who has been complaining of abdominal pain for six months.

Examination of the blood, urine, and stool, should be carried out as part of the initial visit. Some of the vague blood dyscrasias may play a rôle in the causation of abdominal pain. Repeated leukocyte counts and sedimentation tests may be of assistance in diagnosing those conditions due to a rheumatic infection. The importance of urinary tract infections as a factor in the production of abdominal pain is fairly well stressed. However, their diagnosis will not be made unless the urine is examined. That dark-colored stools due to the presence of occult blood are probably the most constant finding in duodenal and gastric ulcers is important. Intestinal para-

sites are probably not so common a factor as thought, but must necessarily be considered.

Tuberculin testing is an easy procedure to carry out and should be made routine in examination.

Constipation is frequently responsible for abdominal pain and when present, corrective methods should be advised. Intestinal spasm, either as an accompaniment of constipation, or as a separate entity, can be excluded by the failure of the symptoms to respond to belladonna and a low residue diet.

After the cases have been thoroughly and systematically studied as above outlined, and with no definite cause being found, and with a failure of the symptoms to respond to a regulation of diet and life, investigation of the gastro-intestinal tract by roentgenography is indicated. Pyelographic studies should be advised where renal calculi and anomalous conditions of the urinary tract might be suspected. Biliary calculi are comparatively rare, but when a possible factor gallbladder visualization might be of assistance.

The great majority of causes of low-grade abdominal pain in children are undoubtedly comparatively trivial. This fact has given rise to the unfortunate tendency on the part of the physician to adopt the line of least resistance and classify all cases as due to one or the other of these trivial factors. As a consequence when confronted with a problem that fails to fit into his limited category, he is very much at a loss. This is a most unfortunate situation, as one will make less mistakes and more correct diagnoses if the policy of exhaustive thoroughness is adopted.

### THE TREATMENT OF ACUTE NEPHRITIS AND ITS COMPLICATIONS IN CHILDHOOD

SINCE there are so many classifications of nephritis in childhood it is well to define the term "acute nephritis" as used in the title. We speak of that condition which usually, if not always, follows an acute infection and is termed by various writers "acute glomerular nephritis," "acute hemorrhagic nephritis," "acute postinfectious nephritis," "acute focal nephritis" and "acute diffuse nephritis." The symptoms and course of this general systemic disease are too well known to warrant discussion here, but for purposes of clearness it is well to give the characteristics which serve to distinguish it from other types of nephritis. The sudden onset follows a few days or a few weeks after an acute infection but the symptoms may begin while the infection is still present. Edema, seldom extreme, is nearly always recognizable, and hypertension is the rule, although it may not be severe. The urine is reduced in amount and contains albumin, pus and many granular and cell casts. Blood is always present, usually making the urine smoky or brownish red. In children there is a tendency to complete recovery.

Since the disease under discussion is preceded by acute infection elsewhere in the body the treatment naturally begins with the treatment or elimination of this infection. It is well known that the  $\beta$  hemolytic streptococcus plays an important rôle in acute nephritis which condition often follows acute streptococcal respiratory infections, scarlet fever and other disease in which this organism is present. Localized infections, such as otitis media, mastoiditis, osteomyelitis and erysipelas,

as well as the more generalized infections may be complicated by the development of nephritis. Another type of infection common in childhood and often disregarded as an antecedent to acute nephritis is impetigo contagiosa. In our experience many children with acute nephritis have had this as the only demonstrable preceding infection. Although the  $\beta$  hemolytic streptococcus more often than any other organism is implicated in acute nephritis, one must not lose sight of the fact that both the pathologic and clinical pictures of the disease can be produced by other organisms or their by-products, such as the  $\alpha$  streptococcus and the pneumococcus. Adequate care of these predisposing infections does much to prevent acute nephritis.

When there is a localized lesion, such as an abscess or acute otitis media, surgical treatment should be instituted. Adequate drainage of such an infection lessens the opportunity for the absorption of toxins and hence there is less likelihood of subsequent acute nephritis. The proper care of these infections may cause dramatic improvement in an already existing nephritis; thus the presence of kidney damage is indication for the radical treatment of such a localized lesion.

In recent years many sera have been developed for the treatment of streptococcal infections, and there is some evidence to show that in such diseases as scarlet fever and erysipelas their use is followed by a decreased incidence of nephritis. It would seem wise, therefore, to use serum in severely intoxicated patients suffering from scarlet fever or erysipelas. This same theory would apply to the use of serum in pneumococcal infections when the causative organism can be typed and found to belong to one of those groups for which adequate serum is available.

At present the whole therapy of streptococcal infections is undergoing a rapid change because of the introduction of a drug which seems to be more or less specific against this organism. This chemical, para-amino-benzene-sulfonamide, or sulfanilamide, if given in doses large enough to raise its concentration in the blood to between 5 and 10 mg. per 100 cc. causes the great majority of infections due to the hemolytic streptococcus to disappear rapidly. If the early optimistic reports on the use of this substance are borne out by later

investigations it will doubtless be a valuable aid in the prevention of acute nephritis as a complication of streptococcal infections. So far no one has demonstrated any harmful effects to the kidneys resulting from the use of this drug in therapeutic doses. Therefore, it seems reasonable to employ it even during the presence of nephritis if there is a coincident infection with the hemolytic streptococcus. When this is done it must be remembered that para-amino-benzene-sulfonamide normally excreted through the kidneys may be retained within the body and that its concentration in the blood may rise more quickly and to greater heights than it would if the kidneys maintained their normal excretory function. Therefore, the dosage should be controlled by frequent blood analyses with the purpose of maintaining a concentration near the therapeutic level and preventing the accumulation of the drug in the blood stream to the point of producing toxic effects, such as sulf-hemoglobinemia, hemolytic anemia, fever, acidosis and skin rashes. As yet no reports are available concerning the use of this chemical in acute nephritis.

In the enthusiasm for new therapeutic measures, particularly for things which seem to be specific, we must never lose sight of the fact that the normal processes of body defense and body repair should be fostered. *Vis medicatrix naturae* must ever remain a strong adjunct to any form of therapy, and there is no question but that good hygienic care, protection from exposure, proper nursing and carefully guarded convalescence during infections will lessen the likelihood of acute nephritis as a complication.

#### TREATMENT

In treating a child with a mild or average case of acute nephritis little more is needed than good nursing care. The prognosis is excellent when the condition is uncomplicated, and the vast majority of the patients recover quickly, completely and without sequelae. This happens under therapeutic régimes that vary tremendously. Rest in bed is important and should be continued as long as appreciable amounts of blood or albumin are present in the urine. Occasionally when convalescence is slow and a trace of albumin in the urine is the only remaining evidence of a preceding acute nephritis, it is

safe to allow the patient to be up and about if this increased activity does not cause a relapse or reappearance of other symptoms of the disease. A good deal of attention has been paid to the clothing and body heat of patients suffering from this disease. At one time it was considered wise to produce excessive sweating by the use of blankets and artificial heat. Later work indicates, however, that when water is eliminated by this route there is no appreciable loss of the abnormal toxic products and the chief effect, aside from making the child uncomfortable, is the loss of water needed for renal secretion. It is equally important not to allow the patient to become chilled as the resulting renal vasoconstriction may have the effect of intensifying the symptoms of the already existing nephritis. Children with this disease, then, must be clothed so that they are comfortably warm but not sweating.

The question of diet in the treatment of nephritis has provoked much study and many types of feeding have been tried, varying from virtual starvation of the patient for a period of many days to forcing a full diet with emphasis on proteins. The amount of protein given to patients with scarlet fever and other streptococcal infections bears no relationship to the occurrence of nephritis. Likewise, it is the opinion of many clinical observers that the quantity of protein in the diet during acute nephritis has little if any effect on the natural course of the disease. It has been our custom to give these children light, nourishing, easily digested food with no special limitation of protein, fat or carbohydrate but with no more sodium chloride than is necessary for palatability. During the first few days of the disease if nausea is present, no particular effort is made to make the child eat. An alkaline ash diet is considered beneficial by some. We have been unable to see any striking evidence of this but usually give fruit juices freely since they are well tolerated by young patients. In cases where the continued loss of albumin in the urine results in a lowered blood protein it is wise to increase the protein in the diet in an effort to recover this loss. This is especially true if the level of blood protein is low enough to cause edema. However, in acute nephritis this is rarely the case except where children have been on a poor diet for a long time or where the nephritis has advanced into the subacute or chronic stage.

The question of fluid intake has caused even more discussion than that of diet. There are two opposing points of view on this subject, those adhering to the one feel that fluids should be limited as much as possible in order to spare the kidneys additional work, and that the body, already edematous, has a sufficient reservoir of fluid to supply the blood stream and the kidneys with enough water for all the elimination of which they are capable. Others hold the opposite view that since acute nephritis is due to a circulating toxin secondary to some infection, the dilution of this toxin and its excretion are necessary before there can be an improvement in the capillary and hence the renal lesion and, following this, an increased ability of the kidneys to excrete. Adherents of this latter viewpoint believe in forcing fluids by mouth if possible, or by needle if necessary, to the point of several liters a day. It seems logical to adopt a more or less middle ground and to give these children a reasonable amount of fluid, probably very close to their normal intake, of from 1 to 3 liters a day. If there is nausea or loss of consciousness, making it impossible for the patient to take sufficient fluid by mouth, even in the presence of moderate edema, one should give intravenous glucose. This supplies to the blood stream both water for the promotion of renal excretion and glucose which furnishes a readily available food and prevents the ketosis incident to starvation. The glucose may possibly act as a detoxifying agent and also as a direct myocardial stimulant. Administration of physiologic saline is necessary only when there is a depletion of body electrolytes indicated by a low total base or low blood chloride.

Specific medication is not available, and again it is well to emphasize the fact that acute nephritis is primarily not an infection of the kidneys alone but a general systemic disease. It is unwise to use irritant diuretics in the presence of hemorrhagic nephritis. More harm is likely to follow their use than benefit to be derived from a slight temporary increase in the amount of urine excreted. When patients are uncomfortable it is safe and wise to give them an analgesic such as acetylsalicylic acid and for those who are restless, delirious or convulsive more powerful sedatives, such as paraldehyde, chloral or morphine may be used. Magnesium sulfate has been more valuable in the treatment of acute nephritis

than any other substance we have tried and we now give it to almost all patients with this disease. When there are no cerebral or cardiac complications and when there is no nausea it can be given by mouth in doses of from 5 to 25 Gm. every four hours, depending on the size of the patient. This can be kept up until there is a marked diarrhea or until the hypertension has decreased to within normal limits. If the drug cannot be taken by mouth, it is well absorbed by rectum in a 4 per cent solution or it can be given intramuscularly in a 25 per cent solution of the crystalline salt in doses of 0.1 Gm. per kilogram of body weight, from twice to six times daily depending on the severity of symptoms.

### COMPLICATIONS

The most serious complication of acute nephritis, if it can be called more than a severe symptom, is involvement of the central nervous system, with resulting restlessness, convulsions and coma. Hypertension almost always accompanies this group of symptoms. These manifestations of cerebral edema and irritation usually occur early in the disease and at times develop with great rapidity, so that careful observation and prompt treatment are most important. The aims of treatment are twofold; one, to decrease the cerebral edema and increased intracranial pressure as quickly as possible; and two, to lower the blood pressure which may be very high when this complication sets in. Lumbar puncture has long been used as a means of stopping uremic convulsions. Since the withdrawal of fluid below the edematous base of the brain may cause pressure on the medulla and result in respiratory failure, extreme care must be exercised in the performance of such a therapeutic puncture. Although it is a method of last resort it may be a valuable one but should be used with extreme caution. Occasionally good results follow the intravenous administration of hypertonic glucose. However, it is not unlikely that cerebral edema of an even severer degree may develop some hours later after the initial osmotic effect of the increased blood sugar has disappeared, so that the end-result is not always satisfactory. Again magnesium sulfate has proved to be a most valuable therapeutic weapon and seems to exert its effect both in decreasing the edema and relieving the general arteriolar spasm.

When convulsions are severe and intractable to the ordinary therapeutic measures, especially if the blood pressure is very high, magnesium sulfate may be given intravenously as a 1 per cent solution of the crystalline salt in quantities varying from 0.1 to 0.2 Gm. per kilogram of body weight. Extreme care must be exercised when the drug is used in this manner for both respiratory and circulatory collapse may occur. The blood pressure should be taken frequently while the fluid is run into the vein at the rate of 1 to 3 cc. per minute. As soon as a fall in systolic pressure of 10 to 20 mm. of mercury occurs or if the respirations become shallow or irregular administration should stop. It is important that calcium gluconate be available for immediate use as an antidote if symptoms of magnesium poisoning appear. The most satisfactory way to give magnesium sulfate is by intramuscular injection of a 25 per cent solution of the crystalline salt which may be given in doses of 0.1 Gm. per kilogram of body weight every four to six hours until improvement occurs or until the blood pressure descends to a normal level. As soon as improvement begins it is well to give the drug by mouth and stop the intramuscular injection. Sometimes sterile abscesses are produced especially when the fluid gets into the subcutaneous tissue. It is important to watch these patients carefully and to resume the more drastic treatment should convulsions recur, drowsiness increase, or a marked rise in blood pressure return. If the improvement in cerebral symptoms is accompanied by an increase in kidney secretion it is unusual to have a relapse.

The other serious complication of acute nephritis in childhood is myocardial failure, which is present to some extent in about 15 per cent of the patients admitted to the hospital with acute nephritis. It usually comes on after the nephritis has been present for several days and is manifested by an increase in edema, dyspnea, tachycardia, enlargement of the heart and the other well-known signs of heart failure. Here again, early treatment may prevent a fatal outcome. Hypertension is nearly always present in these cases, its sudden development being one of the principal reasons for failure of the heart muscle. therefore, it is important to lower the blood pressure as soon as possible. It is probable that spasm of the smaller arteries is an important causative factor, hence, the intramus-

cular administration of magnesium sulfate, as outlined above, should be instituted at once, and continued until the blood pressure becomes normal or, at least until cardiac compensation is reestablished. We have found it helpful to give these patients hypertonic glucose by vein every few hours, an average dose being 50 cc. of a 20 per cent solution, given over the course of fifteen to twenty minutes. Digitalis has also been valuable but it must be remembered that since the kidney excretion is diminished the usual rules for digitalization may not hold. One must proceed with great caution in administering the drug, being constantly on guard for the appearance of toxic manifestations. One child under our care was given less than his calculated digitalizing dose and continued to have signs of intoxication for five days after the drug was stopped. Morphine in full doses often helps to quiet these children. The presence of cyanosis is an indication for oxygen, and we have seen extreme restlessness in a cyanotic child relieved more quickly by oxygen than by all the other means mentioned above. Venesection with the removal of from 100 to 200 cc. of blood may be followed by a dramatic improvement and may allow sufficient time to institute more permanent therapeutic procedures.

It must be remembered that when the heart fails in the presence of acute nephritis the patient is in a serious condition where every means at hand must be used to break the vicious circle. As much as we would like to test the efficacy of a single drug or the relative value of different drugs in treating this complication we are not justified in omitting those tried and proved measures for the relief of a failing heart. Delay may mean death, and a break in the progressive train of symptoms usually points toward complete recovery.

After a child has recovered from acute nephritis it is well to be sure that any existing foci of infection, particularly the tonsils and adenoids, are eliminated. It is also wise to give such a child additional bed rest during respiratory and other infections which may occur in succeeding months, and protect him from undue exertion and exposure.

## CLINIC OF DR. LEON FREEDOM

FROM THE DEPARTMENT OF PATHOLOGY, UNIVERSITY OF  
MARYLAND

---

### PROGRESSIVE BIRTH PALSIES

THE term "cerebral birth palsy" is neither a clinical nor a pathologic entity. This term is one used in common for a great number of cerebral pathologic conditions which occur before, during or shortly after birth, and in which some type of motor defective state is found.

The cerebral palsy consists of three major symptoms; namely, palsy, mental manifestations and epilepsy. By "palsy" there is implied a motor deficit involving the pyramidal or extrapyramidal pathways. The former results in pareses or plegias, the latter in chorea, athetosis, etc. The mental picture varies from normal, through a slight diminution of the intelligence quotient to complete amentia. Grand mal seizures occur in about 60 per cent of all cases. They may appear shortly after birth or for the first time many months later.

Many clinicians believe that these birth palsies are caused by hemorrhage or trauma in the newborn. There is often a vague association of the motor defective state with Little's disease. If one is to adhere strictly to the clinical picture as described by Little,<sup>1</sup> then it should be applied only to those cases of cerebral diplegia associated with asphyxia in difficult labor.

This author, in 1853, suggested that difficult labor might be an etiologic factor, but stated that lack of development of the cerebral tissues and meningeal inflammatory processes were the usual causes. Nine years later in a second paper, he stated that nearly three fourths of all cases of spastic cerebral paralyses were caused by intracranial hemorrhage at the time

of birth. He stressed the factors of "birth pressure and intermittent placental respiration."

In 1885, Dr. Sarah McNutt<sup>2</sup> reported a case which she termed "double infantile spastic hemiplegia," the labor difficult and prolonged. A second case report followed in which she generalized meningeal hemorrhage as the cause of all infantile spastic states which dated from the time of birth, and which were associated with difficult labor. Thus Dr. McNutt corroborated the work of Little, and although it has since been shown that she misinterpreted her pathologic observations, and in spite of the numerous contributions to the literature on these cerebral palsies, her teachings have become more or less universally accepted.

Sigmund Freud,<sup>3</sup> 1897, in his monograph proved conclusively that these infantile palsies did not have intracranial hemorrhage as their one common etiologic factor. On the other hand he emphasized too strongly the rôle played by poroncephaly. In 1924 J. Collier<sup>4</sup> maintained that they were all due to a "primary degeneration of the cerebral pyramidal neurones."

These several widely divergent points of view selected from the innumerable contributions to the literature emphasize the striking lack of uniformity in opinion as to etiology and pathologic background, and it is evident that the cerebral type of palsy is not a clinical or pathologic entity.

In the fall of 1932, the author<sup>5</sup> published a paper entitled, "Cerebral Birth Palsies; a contribution to their pathology with a report of a hitherto undescribed form." In this paper, a peculiar progressive cerebral degenerative process was shown to be the background for the clinical picture of a cerebral birth palsy. Keeping in mind the fact that we were not dealing with a stationary cerebral state or scar, the end-result of a previously existing cerebral pathology, but instead with a clinical syndrome which showed evidence of progressive activity, it occurred to us that if we searched carefully enough, we might find among the protean pictures seen in these palsies, cases which might show evidence of clinical activity.

During the past several years, since the study of the autopsy in the above-mentioned case, a series of these defective motor states have been observed. Of these, the several

following have been selected for the purpose of showing progression of symptoms and signs.

The following cases are typical instances of clinical progression. Motor signs may be so slight as to be easily overlooked. If very obvious at birth, the attention of the parents and attending physician is brought immediately to this motor condition. On the other hand, the slow but gradual increase in severity of motorium involvement is such as to be easily overlooked, and only observation over a longitudinal span of months, rather than at any one cross section of the child's life will indicate that the motor disorder is becoming progressively worse.

Moreover, involvement of the basal ganglia pathways may be superimposed upon a pyramidal tract disorder. The reverse may take place, and the disturbance in plastic tone, such as is found in athetosis, may mask the hypertonicity of early cortico-spinal pathway disease. Instead of definite involvement of a limb or extremity, speech might be the cerebral sign of motor disorder. Speech defects (stuttering), with left-handedness, are so frequently associated that this combination is no longer looked upon as mere coincidence. Clinicians recognize the fact that stuttering in a left-handed child becomes worse if the child is forced to be dextrmanual. We have seen several instances of this combination of stuttering in left-handed infants eventually develop into right hemiparesis. This indicates the fact that both the speech and left-handedness must together be considered as signs of defective left cerebral functioning.

The author considers cases of left-handedness, especially when associated with stuttering, as potentially epileptic, for this sequence also has been noted in several instances. The convulsion may occur at or shortly after birth, followed later by motor defect, mental retardation or both. Is it not logical to assume that the same disease which produces the mental signs and convulsions, may spread and affect the motorium? Need the motor signs be present from the very beginning? In the opinion of the author, this prerequisite is essential only from one standpoint and that is purely nosologic; because the same degenerative process may affect any part of the brain and bring about any possible variation in the sequence of clinical

progression. In many of the degenerative cord disorders and system diseases, the usual accepted sequence need not follow classical lines. For instance, amyotrophic lateral sclerosis may begin as a progressive neural atrophy, eventually showing the development of pyramidal tract involvement. Bulbar signs may even precede both the above.

This same clinical variation may occur in the cerebral palsies, in that other phenomena might antedate the motorium signs.

In the selection of these following case reports, only those were used which fulfilled these requirements:

1. Multiparous mother, without instrumentation or prolonged labor, so as to eliminate the factor of trauma to the newborn.

2. Infrequency of convulsions. It is more or less generally accepted that frequent convulsions tend to mental deterioration. Assuming this fact as true, although it has not been corroborated pathologically, nevertheless care was taken to eliminate this factor.

**Case I.**—Normal delivery, mother multipara 4. The family and past history essentially negative. This girl was first seen at the age of four. She was brought in because "she seems clumsy, falls frequently, and is becoming left-handed." The mother states that she did not begin to walk until she was about fourteen months of age, and at a year and a half began to drag her right leg. The mother added, "she never used the right side as much as she used the other. This right leg is getting worse and it's getting thinner. She is just as smart as my other children, but lately, she seems to be getting nervous and irritable and has developed a temper. In the past several months she has voided in bed at night." The history shows that "this child was right-handed at first, but began to use her left hand about six months ago, and now she even eats with her left hand."

The mother was told to keep her under close observation for nocturnal enuresis. It was shown that occasional epileptic episodes occurred at night.

Examination showed a moderately well-nourished and well-developed girl. The somatic musculature was normal, except for slight atrophy of all the muscles of the entire right lower extremity. There was no shortening, but the examination showed a definite motor weakness with a slight increase in muscle tonus. Plantar stimulation produced slight dorsal flexion of the great toe and a tendency to fanning of the smaller toes. All deep reflexes were more active on the right. The mental age was normal, and although this child was alert and cooperative, her misbehavior and psychomotor restlessness were striking. "The temper tantrums are unprovoked and seem to arise for no apparent reason" (psychic equivalent?).

*Sequence.*—Motor (pyramidal tract) defective state, followed by epilepsy and possible early mental manifestations.

**Case II.**—R. M. M., aged fifteen years. Normal delivery, multipara 5. The family history negative. Siblings normal.

After this boy was born it was noticed that he had a peculiar rolling movement of the eyes. Between four and six weeks after birth, the mother stated he did not move the right arm as freely as the other. This weakness gradually progressed, and at four years of age was completely paralyzed in the right upper extremity. At that time he had begun to show signs of weakness in the right leg, and because his attending physician thought that his condition was due to a "blood clot on the brain" a trephine over the right Rolandic region was done but no clot was found. Had several convulsions during the year following the operation, but none since.

He began school at seven. There were repeated failures, and at fourteen he had reached the third grade of a parochial school. Since then he has been selling papers, contributes to his family, and although he appears rather stupid and dull with his I. Q. of 68 he is really likeable and quite cooperative.

The examination shows the following significant findings:

A classical left brachial monoplegia, with marked shortening and spasticity of the fingers in extreme flexion contraction. There is a moderate degree of atrophy of the left lower extremity with typical pyramidal tract signs. The right side of the body is normal.

*Sequence.*—In this case there is a history of progression of right-sided pyramidal tract disease. There is, in addition, a mental retardation associated with epileptic phenomena.

**Case III.**—A six-year-old boy, brought in by his mother who states that "he is my fifth child; he never seemed as bright as any of my other children. He has always had a slobbering of the mouth. He was two years old before he began to walk and he never learned how to talk; never got over that St. Vitus' dance he got when he was less than a year old. At about four months after he was born, he had a convulsion. He was constipated at that time, but he didn't have fever and he didn't look sick. After the doctor gave me some medicine for his bowels (milk of magnesia), he never had any more convulsions. As he grew older, up to five, the jerks grew worse, and then he began to get those twisting movements like he is now. The visiting nurse told me I ought to send him to Rosewood (an institution for feeble-minded) but I didn't want to send him there until I was sure nothing else could be done."

Two months ago he began to have daily grand mal episodes. The mother stated, "since he has been taking your medicine (bromides) the spells aren't so bad but those jerky twisting movements are the same as ever."

Examination shows this youngster to be oligophrenic. Continuous chorea and occasional athetoid movements, mostly present when standing or lying down. There is a definite diminution in plastic muscle tonus, permitting excessive stretching at the joints. This corresponds to the classical picture of chorea as described by O. Foerster.\* At other times during the athetosis there is a marked increase in plastic muscle tonus.

*Sequence.*—An amentia, followed by motor manifestations of an extrapyramidal type, with onset of epilepsy at six. There is progression of chorea to athetosis, a possibility described by A. Jakob.<sup>7</sup>

**Case IV.**—An eleven-year-old colored girl seen in the neurologic outpatient service of the Provident Hospital. A multiparous mother,<sup>6</sup> who is intelligent and cooperative. The patient was the third born. No history of difficult labor or instrumentation. This child had spasms shortly after delivery; these continued for about six months, ceased, and at three years of age she had one seizure. The mother states that "she never used her left arm the way she should, but when the spasms stopped, the arm got worse and then she began to have trouble with her left leg." She began to walk at two and one-half, and started to talk at the same time. At about three years of age, when she began to get about fairly well, the mother observed that "both of her legs, especially the left, seemed stiff. The right leg began to get bad when she was about seven, nearly eight, and lately, both arms are like that."

The examination shows a moderately well-nourished colored girl, whose appearance does not suggest her low mental age (six years). The neurologic status—a typical spastic diplegia (tetraplegia), with marked hypertonicity and the classical pyramidal tract involvement signs. The gait is typically scissors type. The blood and spinal fluid are negative.

*Sequence.*—Convulsive seizures in a mentally deficient girl but with striking progression of pyramidal tract involvement.

**Case V.**—Five-year-old boy, the third of 5 children, brought in because of difficulty in walking. The family history is negative, except for a male sibling who died shortly after birth (cause not known). The mother first noticed that his locomotion became increasingly difficult at about three years of age. Any attempt to stand was attended by marked increase in extensor tonus of both extremities, the youngster standing on his toes. At five years of age, this boy had progressed into a typical spastic diplegia. About eight months ago "the trouble began in his arm, in that he failed to use the left arm as much as he did formerly."

Examination showed in addition to classical diplegia, hyperactive deep reflexes with Hoffmann's sign in the right and a supranuclear type of right-sided facial involvement. There are no convulsions, nor is there any impairment of mental age.

*Sequence.*—Progression of pyramidal tract symptomatology without epilepsy or mental change.

#### COMMENT

These cases have been selected from a series of 34 observed during the past several years. Pyramidal or extrapyramidal tract types of motor disturbances are common to all. The motor changes may be obvious at the time of birth or may have first been noticed many months later. In several of the cases there is definite intelligence deficit. This is brought to the

attention of the mother usually at about the second year. chiefly because the child has failed to learn to talk. Convulsive states are almost a constant accompaniment, so much so as to be accepted as an integral part of the syndrome.

The most widely accepted theory as to the etiologic factor is birth injury, with either intracranial trauma or hemorrhage. Schwartz<sup>8</sup> found hemorrhage and softening in 65 per cent of 300 cases. Cornwall<sup>9</sup> discussed meningeal intracerebral and subdural hemorrhage, as well as sinus thrombosis as causes of infantile palsies, stressing subdural hemorrhage incident to tentorial tear as causing extravasations of blood into the soft brain substance.

Another widely accepted theory is that these palsies are caused by poroncephalic defects. There is considerable discussion as to the nature of the poron or cavity formation. It is traumatic. Jaffee,<sup>10</sup> secondary to a polioencephalitis (Sachs and Peterson<sup>11</sup>); according to Heschl who, in 1859, first introduced the term of "poron," considered them as due to either faulty development during intra-uterine life or to retrogressive changes incident to vascular occlusion (quoted by Schob<sup>12</sup>). J. H. Globus,<sup>13</sup> in 1 case, thought that it was due to a prenatal encephalitic process which progressed after birth.

Collier<sup>14</sup> maintained that these palsies are due to a "primary degeneration of the neurones," but those who work in neuropathologic laboratories have seen the clinical picture of cerebral birth palsy in such widely varied pathologic states as congenital maldevelopments, amaurotic idiocy, infantile cases of diffuse subcortical sclerosis belonging to the group of per-axialis subcorticalis diffusa.

There are also purely degenerative conditions in which the bulk of the pathology lies within the cortex; affecting chiefly the upper cortical layers. Cases of this type were described by Spielmeyer,<sup>15</sup> Bielschowsky,<sup>16</sup> Jakob,<sup>17</sup> and Hostermann,<sup>18</sup> under the caption of "Intracortical Hemiplegia" or "Hemiplegie bei intakter Pyramidenbahn."

Papers by Henschen<sup>19</sup> and Schaefer<sup>20</sup> indicate the relationship of vascular disorders to these birth palsies. Congenital anomalies of the nervous system might also produce this picture.

It is logical to assume that an early destructive lesion could

cause either some interference in myelinization or maturation of cerebral substance, but when these disorders have formed a scar the latter cannot possibly account for clinical progression. The duration of secondary degeneration of cerebral axones, from the inception of its end-stage, is approximately nine to ten months. Whatever signs of activity there might be, could logically be explained on this basis only during the first year.

### CONCLUSION

There are among the great group of cerebral palsies in infants, cases in which clinical progression indicating an active process may be noted if care is taken in anamnesis to obtain all the actual facts in chronologic sequence of the course of the disease.

The object of this paper is to direct attention to processual or progressive cerebral disorders. The presence of clinical activity should indicate the possibility of a degeneration of cortex and deeper lying structures, perhaps in the nature of the pathology similar to that seen in the author's<sup>5</sup> case report.

We must keep in mind the fact that degenerative diseases may show activity over many years.\*

Unfortunately, the demonstration of progressive activity does not reveal the nature of the underlying pathology, but it is certainly of value in emphasizing the fact that one is not dealing with a stationary or nonprogressive lesion, thereby eliminating such factors as trauma, hemorrhage and maldevelopments.

From this standpoint the approach to the therapy of certain palsies is obviously not only an orthopedic one, but must find its solution in medicine, rather than in surgery.

## CLINIC OF DR. HARRY M. ROBINSON

UNIVERSITY OF MARYLAND MEDICAL SCHOOL

---

### TREATMENT OF SYPHILIS IN INFANTS

THE treatment of congenital syphilis in infants is almost always a serious problem, complicated as it is by several factors not encountered in adults. One or more of these factors always play a part in the treatment.

Of first importance is the fact that these infants cannot be reasoned with, and cannot understand the necessity of being subjected to regularly administered pain and annoyance.

Secondly, the best treatment, according to our present knowledge of syphilotherapy, requires "needle" treatments which always, even with the most efficient technic, cause pain.

Thirdly, the vast majority of congenitally syphilitic children are born of parents of a low stratum of society, frequently ignorant, who themselves rarely understand the full implication of the disaster which has befallen them and their offspring, and who frequently cease not only their own treatments but those of the child, because they cannot tolerate the baby's crying when it is hurt by the needle.

Finally, and of extreme importance, is a consideration of the parents' financial status and, often, of their inability to pay for their own treatments and for those of the infant. Treatments, even at 25 to 75 cents each, become in many instances a hardship, and in explanation of their lapse in treatment, they say that it is easier to do without treatments than without food.

These problems must be met, and every effort made to overcome them through an understanding social service department and a considerate, able physician, properly trained in the technic of the administration of the drugs.

The parents must be consoled, and constantly reminded that without this treatment the infant may never attain a condition of normalcy; nor must the physician permit his staff to become irritated or annoyed by the crying infants; this may lead to careless work and indifferent handling of the case. Their care is a duty we have to perform to the best of our abilities and we should never lose the sympathetic feeling for these unfortunates.

#### THE DRUGS USED

There are four types of drugs which we use in the treatment of congenital syphilis: arsenic, bismuth, mercury and the iodides.

Sulfarsphenamine, a trivalent arsenical, is the form in which arsenic is usually administered. It is the only arsphenamine that can be administered intramuscularly with very little pain or consequent induration. This is of extreme importance because, up to the age of two years, venipuncture, while possible and regularly practiced by us in obtaining blood for serology, is not feasible as a means of giving treatment. As a consequence, almost all therapy to infants is by intramuscular injection. It has been advised that the dose be measured by weight<sup>1, 2</sup> of the infant and that this dose should be approximately 10 to 20 mg. per kilo of weight. We have not always found this a desirable means of computing the dose because of reactions; therefore, as an arbitrary dose, we give infants up to three months of age, of an average weight, 0.025 Gm.; from three to six months of age, 0.05 Gm.; and from six months to one year of age, 0.1 Gm. Concentration of solution is of importance also, and the more concentrated the solution, the less pain is experienced; the dilution of 0.5 Gm. in 1 cc. is preferable and the dose can easily be gauged by a tuberculin syringe.

In late congenital syphilis it is preferable, where intravenous injections are possible, to use neoarsphenamine (in a dilution of 0.1 Gm. in 2 cc.), or silver arsphenamine (in a dilution of 0.1 Gm. in 5 cc.), instead of sulfarsphenamine. In white patients, silver arsphenamine must be used cautiously as it can cause a peculiar leaden-colored type of argyria. One may use it in negroes without concern as such discoloration cannot be noted. In the older children we have found these

drugs to be more effective and less reactive than sulfarsphenamine. In these older children, we disregard the rule of dosage by weight, which is usually prescribed as 10 mg. per kilogram of weight, and generally administer to children, of average weight, from two to four years of age, 0.1 Gm. to 0.2 Gm. of neoarsphenamine, or 0.05 Gm. to 0.1 Gm. of silver arsphenamine; and from four to ten years of age, 0.25 Gm. to 0.3 Gm. of neoarsphenamine or 0.1 Gm. to 0.15 Gm. of silver arsphenamine.

Under certain conditions, specifically where "needle" treatments are inadvisable, due to extreme terror or "nervousness" of the patient, one may administer stovarsol (acetarsone) by mouth. This drug, given by mouth, is spirocheticidal, destroying surface organisms generally within twenty-four hours; but, as it is a very toxic drug, frequently causing dermatitides and also increasing the icteric index, it should be administered with great care, never letting the guardian have more at any time than is sufficient for three days' to one week's treatment, and cautioning the guardian about the drug's toxicity; that is, impressing upon the guardian the need for reporting to the attending physician any reactions, such as itching, skin eruptions, yellowing of the skin and eyes, diarrhea, etc. The dose of this drug is approximately 0.1 to 0.25 Gm. daily for two weeks, followed by a rest period of one week, using mercury inunctions during this interval.

Bismuth is the next drug in point of usage and has almost completely replaced mercury. In our experience bismuth subsalicylate (18 to 20 per cent suspension) has proved an effective drug, causing little pain if properly injected. In place of this, one may use a bismuth preparation soluble in oil or one soluble in water. The dose of bismuth subsalicylate as prescribed by us is, to infants up to six months of age, 0.05 Gm.; from six months to four years of age, 0.1 Gm. In our experience these comparatively large doses have been well tolerated without skin, gingival, or other reactions.

Mercury, although the oldest drug in point of service, is not used as often as bismuth. Rarely, in patients whose disease is resistant and does not respond to sulfarsphenamine or bismuth, mercury inunctions have accomplished the desired results. Unguentum hydrargyri, 30 to 50 per cent, is the

preparation of choice and about  $\frac{1}{2}$  to 1 drachm is used once a day, either by rubbing the ointment into the skin or by putting it on the belly band and permitting the actions of the infant to rub it in.

The iodides are rarely used in our clinic, as they are of no use in early syphilis and of little use in late congenital syphilis. If and when used, we prescribe the saturated solution of potassium iodide, giving rather large doses (as compared to adults), namely, 5 to 10 drops three times a day.

#### PLANS OF TREATMENT

In order to rationalize our system of treatment of syphilis in infants, we have grouped our plans of treatment under the following headings:

Preventive (prenatal care and treatment).

Curative (in early congenital or acquired syphilis).

Arrestive (in late or tardive congenital syphilis).

Supportive.

**Preventive Treatment.**—There can certainly be no questioning the statement<sup>3, 4</sup> that the supreme method of treating congenital syphilis is to prevent it. To do this we must utilize every instrument and method at our command to detect syphilis in the pregnant woman. There have been loud and foolish outcries against performing routine serologic tests for syphilis (Wassermann tests and flocculation tests) on pregnant women, some physicians insisting that this was prying into the private affairs of good women. Unfortunately, occasionally such physicians have had to dishonestly explain away an infected, macerated infant, miscarriage, or full term syphilitic child. Williams<sup>3</sup> was among the first to show that adequate antisyphilitic treatment administered to the expectant mother was ample assurance of a live infant, often entirely free from the disease. McKelvey and Turner<sup>1</sup> reported that if treatment were given as late as the eighth month and carried through to delivery, life expectancy was markedly raised. Our experience has confirmed these findings, and it is indeed rare to report the birth of a syphilitic infant, if treatment is begun in the expectant mother between the fifth and six months. Such treatment consists of alternating series of weekly injections of one of the arsphenamines, intravenously, and a bismuth prep-

aration, intramuscularly. That is, an arsphenamine treatment (arsphenamine 0.3 to 0.4 Gm., or neoarsphenamine 0.6 Gm. or mapharsen 0.06 Gm.) is given once a week for eight weeks. Then, without a rest period, the patient receives weekly injections of a bismuth preparation for eight weeks, and these alternate series of injections are continued until delivery and are resumed as soon as practicable after delivery until the patient has received one and one-half years of consecutive weekly treatments. If the syphilitic infection is not detected until the sixth or seventh month, it is desirable to administer the first few treatments of bismuth and an arsphenamine (about four or five) concurrently, or if the interval between the commencement of treatment and delivery is only between eight and twelve weeks, we have noted better results by administering both the arsphenamine and bismuth drugs concurrently until delivery. It should be emphasized, however, that even 2 or 3 treatments of arsphenamine and bismuth, administered concurrently immediately before delivery, will noticeably raise life expectancy. To accomplish the best results, treatments should be begun as early in pregnancy as possible, and that can only be brought about by the routine use of the serologic tests for syphilis (the Wassermann or complement fixation and the flocculation or precipitation tests) for the detection of the disease when otherwise unrecognizable. In the "best" stratum of society, syphilis is present to the extent of 1 per cent, and in others, the percentage ranges from 7 to 30 per cent. It is a misfortune to be afflicted with this disease and a large proportion who are so afflicted have contracted it innocently. Therefore a greater effort must be made to prevent the transmission of the disease to the offspring, most innocent victim of all.

It is questionable whether a woman, adequately treated before, or during and after one pregnancy needs to be treated during each succeeding pregnancy. In most instances I have found it to be unnecessary, provided the patient has not become reinfected.

**Curative Treatment.**—Infants acquire syphilis from external sources, either genitally or extragenitally. Those infected genitally are usually victims of a superstition, principally among very ignorant negroes and whites, that if he (it is al-

most always a male) can have coitus with an infant of any sex or a virgin he will transfer the disease to the other party and be himself cured. Most of such transferred infections have been in negro infants. The most frequent infection extragenitally, in our experience, has been on the lips from kissing; of the latter, one interesting case may merit report: asked to see an infant eight months old because of a lesion on the upper lip, we found this lesion to be a chancre and demonstrated *Spirochaeta pallida*. Everybody except the mother was suspected, as her blood Wassermann and examination had been negative before and immediately after delivery. But as all other contacts were negative, the mother was reexamined and found to have early secondary syphilis, Wassermann positive. She had contracted the disease from her husband, after the birth of the child, and in kissing the child had infected it.

As the treatment of acquired syphilis and early congenital syphilis in infants is the same, these will be considered together. To accomplish a cure in early congenital syphilis, it is necessary to detect the presence of the disease at the earliest possible moment, preferably before the age of two months, and to treat intensively.

There are those who contend that all infants born of syphilitic mothers should receive a full course of antisyphilitic treatment, even though no evidences of the disease are detectable in the child, and regardless of whether or not the mother has received adequate antisyphilitic treatment. This is a difficult question to decide, but as, in our experience, so many infants born of adequately treated syphilitic mothers remain apparently free of the disease, clinically and serologically, it seems unnecessary to torture those who are nonsyphilitic and do not require treatment, in order to make sure that every syphilitic infant may receive necessary treatment.

As a rule, we have required a definite diagnosis of syphilis before instituting treatment. The history of syphilis in the mother has aroused our suspicions concerning the child, and repeated, consistent efforts have been made to confirm this suspicion to certainty or to completely remove the stigma.

It is required of those attending deliveries that all placentas from syphilitic mothers be carefully examined histologically for evidences of the disease. Cord blood is no longer examined

as it was shown by Fildes<sup>5</sup> not to be indicative of syphilis in the infant. From the work of Cooke,<sup>6</sup> Dunham,<sup>7</sup> and Faber and Black,<sup>8</sup> it is to be noted that a positive blood in the infant that reduces in titer week by week is probably only a "carry over" from the mother and not indicative of syphilis in the infant. All such positive bloods are followed by weekly blood examinations until proved either conclusively positive or negative. It is much better to wait a little longer, until the serology is definitely and persistently positive before embarking on one and one-half to two years of "needle" treatments. It has lately been shown by Caffey<sup>9</sup> that the chondro-epiphyseal lines demonstrated by roentgenograms, formerly believed to be syphilitic, are now known to be due frequently to a bismuth deposit absorbed from the mother's treatment.

In the final analysis the infant's blood, therefore, remains the most reliable indicator as to the presence or absence of syphilis, and repeated examinations should be made in the early weeks of the infant's life, in the effort to diagnose the presence of syphilis as early as possible, preferably by or before the second month of life. Of course, if any lesions are present, such as bullae, papules, erosive lesions (mucous patches or condylomata lata) no further confirmation of the diagnosis is required than a dark-field examination demonstrating *Spirochaeta pallida*. Treatment begun at this early date and continued for a period of twenty-four months will insure a cure in a large majority of the cases.

The treatment consists of alternate series of weekly intramuscular injections of sulfarsphenamine (15 mg. per Kg. of body weight has been prescribed, but our dosage is arbitrarily usually 0.025 Gm. to infants of average weight, up to four months of age; 0.05 Gm. for infants from four to eight months of age; and 0.1 Gm. for those from eight months to one and one-half years of age), and bismuth subsalicylate in oil (also intramuscularly, 0.05 to 0.1 Gm.). Treatment is continued until the serology is negative and all clinical evidences have disappeared, and for one year thereafter, usually constituting one and one-half to two years of consistent, consecutive weekly treatment, *without* rest periods, unless lapses in treatment are mandatory due to the unsatisfactory condition of the patient.

Before discharging the patient on probation, the cerebrospinal fluid should be examined. Observation should be continued for years, preferably to adulthood. It is doubtful whether a "cure" will prevent the appearance of the stigmata usually seen in late congenital syphilis.

**Arrestive Treatment.**—Opinions differ as to whether treatment will prevent the appearance of clinical evidences of the disease. Igersheimer<sup>10</sup> asserted that, with or without treatment, both cornea were almost invariably involved, sooner or later. On the other hand Carvill and Derby,<sup>11</sup> and Robinson,<sup>12</sup> found that adequate treatment, instituted when the interstitial keratitis involved only one cornea or neither, prevented the infection from appearing in the other cornea, or at all.

In all patients in whom it is permissible, we administer alternate series of either arsphenamine, neoarsphenamine, mapharsen, or silver arsphenamine, intravenously, and bismuth subsalicylate intramuscularly. As previously mentioned, caution is necessary concerning silver arsphenamine, which may cause a peculiar leaden-colored type of argyria if used for more than two series of eight injections. It is preferable therefore to use this drug carefully *or* only in negroes.

In this stage of the disease (late congenital syphilis), treatment should be continued from one and one-half to two years and then terminated, the patient being told to report once a year for a physical examination and blood test. The serology is almost invariably positive at the end of treatment and will probably remain so as a Wassermann fast reaction. I have known such patients to receive from some physicians consecutive weekly treatments for five years or more without change in the serology. Further treatment may be given once a year or once in two or three years, amounting to one or two series each of a bismuth and an arsphenamine at these periodic visits.

Although reactions are not common in early congenital syphilis, they are encountered with moderate frequency in the late type of the disease. The immediate or slightly delayed reactions are usually only annoying and of little moment, but the delayed reactions, especially the dermatitides, jaundice and the blood dyscrasias, should be kept foremost in mind and the patient or guardian questioned at each visit before a treatment.

Even a suspicion of such a reaction warrants temporary (and occasionally permanent) cessation of treatment with the arsenicals. Reactions from bismuth are rarely severe enough to contraindicate further use of the drug.

**Supportive Therapy.**—In those patients with late congenital syphilis who have developed certain destructive manifestations, methods of treatment other than antisyphilitic are required in addition to the regular treatment.

If both corneae are involved and a thick opaque obstructive scar has formed, arsphenamine, bismuth, mercury or iodide treatment is generally ineffective, and, aside from preventing other lesions from forming, is valueless. In our experience old corneal opacities have not been affected or resolved under such treatment. These patients should also be seen and treated by the ophthalmologist. It is possible that, expertly applied, radium or roentgen-ray therapy may be effective in removing or thinning the opacity. This, however, is best judged by the ophthalmologist.

Eighth nerve deafness, when it does occur, has never been relieved in our group of cases. One can only hope that adequate treatment of late congenital syphilis will prevent the occurrence of this manifestation. The otologist, by proper appliances, may aid the patient to put what little hearing is left to the best purposes.

The patient with central nervous system involvement will frequently obtain good results if his condition is detected before the symptomatic phase occurs. Malarial infection therapy (which is our choice) or any other fever-producing apparatus should be used until an adequate number of peaks of temperature have been obtained; this is usually twelve to fifteen; more peaks are desirable if procedures other than malaria inoculations are utilized.

We have used tryparsamide in some of our older patients with very good results, but this should be used only in those cooperative patients in whom a visual field examination can be obtained and only in patients who are believed intelligent enough to complain or tell of dangerous premonitory symptoms, suggestive of amblyopia.

In those patients with central nervous system involvement who have become symptomatic of paresis, commitment to a

hospital for the insane is advised. There, adequate treatment can be given, and if the patient recovers he can be released to continue the necessary adjunct treatment. But if treatment is not effective, he will be where he can receive better attention than anywhere else.

Finally, it should be stressed that to treat the patient is of far greater importance than to treat the disease, and that the wisest admonition is to keep both factors equally and continuously in view.

## CLINIC OF DR. NICHOLSON J. EASTMAN

FROM THE DEPARTMENT OF OBSTETRICS, THE JOHNS HOPKINS  
UNIVERSITY AND HOSPITAL

---

### HEART DISEASE IN PREGNANCY: THE RESPECTIVE DUTIES OF INTERNIST AND OBSTETRICIAN

THERE is general agreement that cases of heart disease in pregnancy are best handled by the obstetrician and cardiologist in close operation. In no other complication of gestation does the obstetrician hang so heavily on the statement of the internist or hazard so much on his advice. Accordingly, it would seem appropriate to outline a few of the facts which the obstetrician expects from the cardiologist in a case of heart disease complicating pregnancy, and at the same time to delineate what seem to me the main responsibilities of each in this important relationship.

The first fact which the obstetrician will want to know is whether the woman has rheumatic heart disease. It will be recalled that several of our standard criteria of heart disease become invalid during pregnancy. Apparent cardiac enlargement, systolic murmurs, accentuation of the pulmonary second sound, shortness of breath on exertion and even crepitant râles at the base of the lungs may be present in pregnant women who have perfectly normal hearts. The diagnosis of heart disease in pregnancy is rendered still more difficult by the mammary enlargement which occurs, a change which makes percussion less reliable and hampers auscultation over certain areas.

The two alterations in the heart during pregnancy which most frequently simulate disease are the change in cardiac outline and the occurrence of murmurs. The former is due in part to mechanical factors, namely, the growing uterus and elevated diaphragm, and in part to an actual increase in the

total area of the cardiac outline. During the last months of pregnancy the growing uterus pushes the diaphragm upward with the result that the heart is displaced to the left, superiorly and somewhat in the direction of the anterior chest wall; at the same time a certain degree of rotation of the heart is believed to take place. These changes are not constant either in degree or direction and vary according to the size and position of the child, the amount of amniotic fluid, the strength of the abdominal muscles and the constitutional type of the thorax. It must also be noted, moreover, that superimposed upon these changes there occurs another and perhaps equally important one and that is an increase in the total area of the cardiac outline. Basing his figures on roentgen ray measurements, Gammeltoft, in 188 cases of pregnancy with no cardiac disturbance, found an increase in the longitudinal as well as the transverse diameter of the heart in 23 cases as early as the fourth or fifth month. This increase became more frequent in the sixth and seventh months, when the longitudinal diameter was increased in 39 cases and the transverse in 33. These measurements were taken at a time when the upward pressure of the diaphragm was of no particular consequence. The roentgen ray studies of Walter Frey are still more convincing. He found among 25 women who were between three and four months pregnant that the transverse diameter of the heart was increased more than 0.7 cm. in 21 cases, or in 84 per cent; while in 10 cases, or 40 per cent, a similar augmentation of the longitudinal diameter was observed. In Klasten and Palugyay's study of 33 normal pregnant women, it was found that the distance from the midline of the sternum to the left margin of the heart was increased on an average 13 mm., and to the right margin of the heart, 3 mm.; these changes were due in part to the shift in the position of the heart and in part to an increase in its apparent size.

Whether hypertrophy or dilatation is the cause of the increase in cardiac outline which occurs during gestation is a moot question. At best, however, the problem is an academic one. From a practical standpoint of view, the conclusions to be reached from these investigations are clear. During pregnancy, as the result of the upward pressure of the diaphragm and the increase in the diastolic size of the heart, the positional

relationships of the heart in the thoracic cavity are frequently changed. The apex beat is moved outward and upward. The left cardiac wall is displaced to the left, a distance which averages about  $\frac{1}{2}$  inch but which may reach almost 1 inch. Therefore, the attending physician must be cautious about making a diagnosis of pathologic cardiac hypertrophy in pregnancy unless it is evident that he is dealing with a very large heart.

The other common alteration in pregnancy which may suggest heart disease, namely, the occurrence of murmurs, is present in from 10 to 20 per cent of gravid women. Various theories have been promulgated to account for these "functional" or "accidental murmurs," none of which are altogether satisfactory. The explanation advanced by Rumpel and Reicher, and subsequently endorsed by Frey, seems perhaps the most reasonable. These authors call attention to the fact that these murmurs do not make their appearance until late in pregnancy, often disappear within a day or two after delivery, and accordingly are to be most logically associated with upward pressure of the enlarging uterus upon the diaphragm and in turn upon the heart. They note also in this connection the observation of C. Gerhardt upon the occurrence of systolic heart murmurs in cases of ovarian cysts; this author not only observed such murmurs, but found that they disappeared when the cysts were tapped and reappeared as the cyst fluid again accumulated. In view of these considerations Rumpel and Reicher studied by means of the roentgen ray the effect which upward diaphragmatic pressure has upon the circulatory structures of the thorax and found that one of the most marked results was a diminution in the size of the retrosternal space. Since this space houses the large vessels of the heart, the authors postulate that these vessels, particularly the pulmonary artery, are brought during pregnancy into closer contact with the surrounding structures and will the more readily transmit the sound of coursing blood to adjacent tissues and thence to the chest wall.

Some plausibility is lent to this explanation if we consider the effect of posture upon the physiologic cardiac murmurs of pregnancy. In a study of 1329 women who were between seven and ten months pregnant, Walter Frey found that 203,

or 30 per cent, presented systolic murmurs when in the recumbent position; whereas only 85, or 12 per cent, showed murmurs when standing. Since he was also able to show by roentgen ray studies that the recumbent position decreased the size of the retrosternal space, he was inclined to associate heart murmurs heard in pregnancy with the diminution of the size of this space and so concurred in the view of Rumpel and Reicher. Aside from their scientific interest, these studies of Frey are of obvious practical importance since they point to the necessity of examining heart murmurs during pregnancy with the patient in the standing as well as in the recumbent posture.

The physiologic heart murmurs heard in pregnancy are rarely, if ever, diastolic in time. It is true that Gammeltoft in his series of 239 normal pregnant women reported diastolic murmurs in a few instances, but it is to be noted that these were heard only over the base of the heart and not over the mitral area. Walter Frey found 2 such cases among 207 women in the latter half of pregnancy. As a general rule, diastolic murmurs are not physiologic, but are evidence of rheumatic heart disease.

In Gammeltoft's study of 239 normal pregnant women, to which we have just referred, he found in 39, or 16.3 per cent, circulatory signs and symptoms of sufficient severity to suggest heart disease. Many of these patients, 24 of the 39, complained of dyspnea during the last months of pregnancy. The urine contained albumin in 19 instances. Edema was present in 34 cases. Physical examinations showed enlargement of the heart, murmurs, extrasystoles, accentuation of the pulmonary second sound, venous pulsations and rapid pulse. The chief complaints of these patients were cardiac pains and distress, headache, and shortness of breath. However, digitalis and rest in bed had no effect upon either the signs or symptoms of these women. When they went into labor, it was impossible, even by the most careful observation, to demonstrate any aggravation of the symptoms during the whole process and when they were discharged two weeks postpartum, practically all the abnormal findings had disappeared. Indeed, the murmurs were no longer audible on the day after delivery.

The report of Gammeltoft is in close accord with that of Hamilton of Boston, who finds that about 7.5 per cent of all

pregnant women coming to the antenatal clinic of the Boston Lying-in Hospital are referred to the cardiac clinic because of symptoms and signs suggestive of heart disturbance. Only about a third of these patients, however, have definite heart disease.

In view of all these difficulties and pitfalls *the conscientious obstetrician will usually hesitate to make a diagnosis of heart disease in a pregnant woman and will depend upon his cardiologic confrère to establish or rule out the existence of this complication.*

The second help which the obstetrician will expect from the cardiologist is in prognosis. Heart disease is a treacherous complication of pregnancy. While the majority of cases go through pregnancy, labor and the puerperium without incident, many follow courses which are difficult to foresee. Between 5 and 10 per cent of the mothers die before the puerperal state is ended.

The prognosis of heart disease in pregnancy resolves itself essentially into balancing the work which pregnancy, labor and the puerperium will impose upon the heart against the cardiac force available to carry out this work. The first of these factors, namely, the work imposed by pregnancy, labor and the puerperium, is of various kinds. In the first place, investigators are in general agreement that pregnancy is associated with a substantial increase in cardiac output, the average increment being about 50 per cent. This is, of course, what one would expect, since during gestation there is a large increase in the area of the circulatory bed due to the growth and vascularization of the uterus. Along with this, a proportionate increase in the total blood volume occurs, in order that the newly vascularized area may be filled. Accordingly, in pregnancy, there is a greater amount of tissue to be supplied with blood and more blood in the circulatory system to be pumped, adjustments which would naturally demand an increase in the minute output of the heart.

This increase in the cardiac output which occurs in pregnancy is a change of fundamental importance. It allows us to dispense with such vague phrases as "the strain of pregnancy" and permits us to speak in quantitative physical terms as follows: as the result of pregnancy the heart is obliged to per-

form on the average 50 per cent more work than it did in the pregravid state. The work involved in labor varies with certain obstetrical factors, notably parity, and if need be, can be reduced to a minimum by operative delivery, that is by low forceps delivery, or, if the cardiac reserve be very depleted, cesarean section. In estimating the work which pregnancy puts upon the heart, social conditions may exert a decisive influence. Thus, a well-to-do woman with a serious heart lesion may, with the help of servants, so minimize her activities during gestation that she will escape the toll which a working woman with a milder lesion would be forced to pay. Finally, the work imposed by pregnancy does not end with the puerperium, for the baby in the crib is sometimes a greater burden than the baby in the womb. The mother must expect for several years the interrupted sleep and the countless additional steps which every infant brings. This aspect of heart disease in pregnancy is seldom touched upon, but must be given due consideration if the problem is to be approached with far-reaching vision.

So much for the work involved in pregnancy and labor. Turning now to the other side of the balance, the cardiac forces available to carry out the work, this estimation is a more difficult one and falls to the cardiologist.

Naturally I do not feel competent to discuss those factors upon which the cardiologist will estimate the reserve forces of the heart but I should like to point out the desirability of the cardiologist and obstetrician using a *common language* when discussing this problem. I know of no better common language than the classification of the New York Heart Association, a classification based on the functional capacity of the heart.<sup>1</sup>

<sup>1</sup> New York Heart Association classification.

"Class I.—Patients with organic heart disease able to carry on ordinary physical activity without discomfort. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea or chest pain. Patients in this class do not show physical signs of congestive heart failure and rarely signs of active heart infection.

"Class II.—Patients with organic heart disease unable to carry on ordinary physical activity without discomfort.

"Class II A.—Activity slightly limited. Ordinary physical activity causes undue fatigue, palpitation, dyspnea or chest pain. Patients in this class rarely show physical signs of congestive heart failure or signs of active heart infection.

Pardee, as well as McIlroy and Rendel of London, have applied this classification to heart disease in pregnancy with eminent success. In actual practice, of course, the placing of these patients in the correct categories is not always simple. Border-line cases are common. While exercise tests facilitate classification, the results are sometimes invalidated by the nervousness of the patient and the strangeness of the movements involved. It is therefore necessary that the functional capacity of the heart be evaluated from as many viewpoints as possible, not forgetting the behavior of the heart in previous pregnancies and labors.

Of course, there are further questions which the obstetrician will wish to put to the cardiologist. For instance, he may wish advice concerning the desirability of prenatal digitalization as a prophylaxis against heart failure in labor and concerning the recognition of early signs of heart failure. However, as I have suggested, *the two principal facts which the obstetrician expects to learn from the cardiologist are: first, the diagnosis of rheumatic heart disease, and second, an estimation of the functional capacity of the heart.* These constitute the main responsibilities of the cardiologist. *To the obstetrician it now falls to adjust the work imposed by pregnancy and labor in such a manner that it can be easily accomplished by the cardiac forces at hand.* This adjusting of the work involved in pregnancy and labor in accordance with the functional capacity of the heart is the main responsibility of the obstetrician.

The manner in which the obstetrician carries out this task will, of course, vary greatly according to the needs of the particular case. With rare exceptions patients grouped in Class I and Class II A may be allowed to go through pregnancy and the first stage of labor; if the second stage promises to be short, spontaneous delivery may be permitted, but if it threatens to

---

*"Class II B.—Activity greatly limited. Less than ordinary physical activity causes fatigue, palpitation, dyspnea or heart pain. Patients in this class usually show one or more physical signs of congestive heart failure, or the anginal syndrome or signs of active heart infection.*

*"Class III.—Patients with organic heart disease and with symptoms or signs of heart failure at rest, unable to carry on any physical activity without discomfort. There is fatigue, palpitation, dyspnea or chest pain at rest. Patients in this class show marked physical signs of congestive heart failure or the anginal syndrome, or signs of active heart infection."*

be long, delivery by forceps is usually desirable. The successful handling of these patients, however, necessitates punctilious prenatal care and constant supervision during labor. It resolves itself into four chief considerations: adequate rest during the whole prenatal period, avoidance of upper respiratory infections, recognition of early signs of heart failure and care during labor. A period of rest in bed in the hospital, preferably for a week or two, is always a beneficial preparation for parturition. With active labor begun, the patient should be placed and kept in a semirecumbent position with the head and shoulders well elevated by pillows. Observations on the pulse and respiration should be made every half hour during the first stage of labor and every ten minutes during the second. A rise in the pulse rate above 115 or in the respiration above 28, particularly when associated with dyspnea, are signs of cardiac embarrassment which, unless checked, may become forerunners of heart failure. Only in the presence of a completely dilated cervix, however, may they be taken as indications for delivery. With the cervix only partially dilated and the patient showing evidence of cardiac embarrassment, there is no known method of delivery which will not tend to precipitate rather than to forestall heart failure. Under these circumstances the treatment is always morphine and digitalis. If this treatment is not effective and the signs of cardiac embarrassment persist or become more marked, it simply means that a grave error in prognosis has been made. Such a patient should never have been allowed to go into labor. Her treatment, as well as her prognosis, is now that of heart failure in labor, a subject which will be discussed shortly.

Patients whose cardiac reserve is so diminished that they have been grouped in Class II B present difficult problems and the obstetrician must reduce to a minimum the work imposed on these patients. Rigorous rules for rest during the prenatal period must be laid down. It is indeed advisable that patients in this group spend one full twenty-four hours out of every week in bed. Should frank heart failure develop during the course of pregnancy it should be an absolute rule that the patient remain in bed in the hospital throughout the remainder of the pregnancy.

The method chosen for delivering patients in Class II B

will depend upon the history of the present pregnancy and the parity of the patient. If there has been no history of heart failure and if the patient is a multipara, delivery by the natural passages may be permissible. In the majority of patients in this group, however, cesarean section will be the procedure of choice. If decompensation has occurred during the present pregnancy, the operation should be done under local infiltration anesthesia. If no recent heart failure has occurred the noninhalation anesthetics are still to be preferred, but "open ether" is permissible. The operation should be performed with the head and shoulders slightly elevated. *Under no circumstances should a patient with heart disease be subjected to the Trendelenburg position.* At the close of the cesarean section the patient should be sterilized by a suitable operation on the fallopian tubes, provided, of course, that the written permission of husband and wife has been obtained.

But at the best, patients in Class II B face considerable risk in childbearing. If a woman in this group has already several living children and presents herself to the physician in the first trimester of pregnancy, it does not seem justifiable to ask her and her family to face this risk. In many such cases therapeutic abortion would seem to be the procedure of choice.

The treatment of patients in Class III resolves itself essentially into the treatment of heart failure in pregnancy, labor and the puerperium. A cardinal fact to be remembered in handling this type of patient is the following: *in the presence of heart failure delivery by any known method carries with it a maternal mortality of over 50 per cent.* Accordingly, the treatment of heart failure in the puerperal state becomes chiefly a medical one, the salient objective being to allay the decompensation. Only when this has been accomplished can one deliver the patient with a fair degree of safety. Occasionally, in patients whose heart failure resists therapy, one is forced to operate in the presence of varying degrees of decompensation, but, as we have already emphasized, delivery under these circumstances carries a grave prognosis. The method of choice for delivering patients in Class III is usually cesarean section under local infiltration anesthesia, but in multiparae spontaneous delivery in bed sometimes yields better results.

Should patients with heart failure start into labor, an

attempt should be made to stop parturition by means of liberal doses of morphine. Even when patients are well into the first stage of labor, it is frequently possible to halt uterine contractions for a sufficient period of time to restore a certain degree of compensation.

In dealing with cases of heart failure in pregnancy the argument is sometimes advanced that "the burden of pregnancy is too much for the heart" and that "removing the load of pregnancy will restore compensation." Were there some magic way of causing the pregnancy suddenly to disappear this might be true. But there is not. The only methods of delivery at our disposal inflict trauma, and when this trauma is superimposed on heart failure, it is enough to kill one half the mothers.

## CLINIC OF DR. HUGH HAMPTON YOUNG

THE JOHNS HOPKINS HOSPITAL

---

### DIAGNOSIS AND THERAPEUTIC INDICATIONS OF VARIOUS DISEASES OF THE PROSTATE

THE prostate is so situated that many accurate methods of examination for differential diagnosis may be carried out with ease. Its proximity to the perineum makes it easily palpable by rectum, and its secretion may be obtained for microscopic examination. Its position around the urethra makes it possible to view the interior of the prostate and to note the condition of its constituent ducts with the urethroscope or cystoscope. Its relations to the bladder may be also studied in a similar way. By means of palpation upon instruments within the prostate, the thickness of certain portions may be accurately determined. With the *x*-ray accurate information can be obtained concerning many details of prostatic disease. The seminal vesicles, which must be included in every study of the prostate, also lie within easy reach and may be studied by similar methods. If it is necessary to see, feel and carry out biopsy upon the prostate, it is easily reached extraperitoneally through the perineum, or through the suprapubic region, and also by means of transurethral operations. There is hardly any organ in the body which can be so satisfactorily studied by so many methods as the prostate.

#### ANATOMICAL CONSIDERATIONS

The prostate is enveloped not only in its own capsule propria, but by two layers of fascia (Fig. 98) which effectively guard against the spread from the prostate to adjacent structures, not only of ordinary infections and tuberculosis, but also malignant disease, for a time at least. These layers of fascia

continue up posterior to the seminal vesicles and vasa deferentia, and thus determine the course in which disease spreads from the prostate. The distribution of the glands of the prostate are important in many ways. Immediately along each side of the urethra are a series of glands, which are the seat of early lateral hypertrophy. External to them is an entirely different group of glands which take little or no part in hypertrophy. Beneath the urethra, and separated from the lateral lobes by a fibrous layer, is the posterior lobe

Fig. 98.—Showing fasciae surrounding prostate, seminal vesicles and ampullae of the vasa deferentia.

or transverse lamella (Fig. 99) which also takes part very rarely in prostatic enlargement, but is by some strange fate the site in which carcinoma usually begins. The median portion of the prostate beneath the vesical neck and anterior part of the trigone is still another separate division which plays a very important part, particularly in obstructive diseases of the prostate. The relation of the bladder to the prostate is very important (Fig. 100). The trigone, as it converges to the vesical orifice, passes down over the median posterior part of the prostate, and is lost in the floor of the urethra. As we

have shown, the trigone plays the initial rôle in micturition. When stimulated by the desire to urinate, contraction of the

trigone pulls the posterior margin of the prostate downward and outward, thus opening a triangular aperture, through which

Fig. 100.—External view of the bladder, prostate, external sphincter muscles of the perineum and anus.

the detrusors force the urine during micturition. The closure of the prostate is accomplished by contraction of lateral muscles, which are easily seen endoscopically when the urethral orifice is opened, and particularly when they contract to draw

the uvula vesicae forward to close the orifice. In the floor of the urethra lies the crista galli, the verumontanum with the orifice of the utricle or vagina masculina, and on each side the orifices of the ejaculatory or wolffian ducts. In certain genital abnormalities the müllerian structures may form a definite vagina, which opens into the urethra at the site of the verumontanum, or in females the müllerian tubercle. In female pseudohermaphrodites, not infrequently, the hymen is found in the floor of the urethra surrounding the opening of the vagina into the urethra or at its junction with the urogenital sinus below. Various abnormalities of the wolffian and müllerian systems lead to complex pictures of great interest. The sphincters are also closely related to the prostate: the internal, we have already described; the external surrounds the apex of the prostate and the membranous urethra. The sphincter medius is an indefinite muscular structure between the two. These sphincters, as we show later, play an important part in the escape of secretion and inflammatory products from the prostate.

#### METHODS OF EXAMINATION

The urinalysis will often give an indication of the condition of the prostate. For this purpose the three-glass test is used. Any secretion from the prostate, which has escaped into the posterior urethra, will be washed out in the first urine passed and found in the first glass. The second urine, passing through a clean prostatic urethra, may be clear and negative, while the third glass, which represents the last urine expelled from the bladder and deep urethra in the final spasmodic act of micturition often contains secretion or shreds from the prostatic or ejaculatory ducts. Secretion, purulent exudates and bacteria in the anterior urethra may also be found in the first urine voided. By cleansing the anterior urethra—that portion which lies between the meatus and the external sphincter—with irrigations or injections of sterile water, one may obtain in the first glass urine uncontaminated by the anterior urethra. It is thus possible to remove the smegma bacillus, which is practically never found in the prostatic urethra. Any acid-fast organisms obtained, especially in the last urine voided after the anterior urethra has been examined, may be recognized as tubercle bacilli. The failure to obtain urine in three separate

glasses has led to many mistakes in diagnosis. By this simple means it is possible to show that the urine which comes from the bladder and kidneys is clear and that the pus found in the first urine voided comes from the urethra, either posterior or anterior.

**Rectal Examination.**—After the urine has been voided in three glasses, as above described, the next procedure is usually to examine the prostate with the gloved finger introduced through the anal sphincter. One should note the condition of the sphincter, whether of normal tone or pathologically relaxed. The condition of the rectal wall—smooth or rough, movable, adherent, infiltrated or ulcerated—should be noted.

Fig. 101.—Case of marked prostatitis and seminal vesiculitis. First degree induration indicated by parallel lines in one direction. Second degree induration indicated by cross lines. Prostate and seminal vesicles are both enlarged. (BUI 8486.)

The prostate, which lies immediately beneath the rectal wall, should be studied by the palpating finger and the results carefully charted. It is usual first to examine the median notch and furrow, then in sequence the left and right lateral lobes, the borders of the prostate, their relations to the external sphincter, triangular ligament and Cowper's glands, the relation between the seminal vesicles, ampullae, the prostate and the structures which surround them.

As shown in Figs. 101 and 102, these findings are recorded on a chart. In Fig. 101 the prostate was irregular, slightly enlarged in places and with induration of first and second degree. One seminal vesicle was enlarged, indurated, second

degree, and the other, first degree. In Fig. 102 is shown a prostate with an oval area of induration of third degree. This isolated enlargement led to the suspicion of either carcinoma or calculus. The latter was ruled out by an x-ray which showed no shadows. These graphic charts should generally be employed, because they give at a glance the findings of the examining finger and contribute materially to the accuracy of the examination and the records.

*x-Ray.*—The x-ray is of great value and, in the simple film, may often show areas of induration indicative of calculus. These pictures should always be taken with the rays directed down the strait of the pelvis, so as to show the prostate unobscured by the symphysis pubis. By dropping the legs of

Fig. 102.—Chart of rectal examination; clinical diagnosis, carcinoma. Radical operation: April, 1914. Pathologic report: carcinoma. Letter (October, 1936): "Well. Urination normal." (Twenty-two years since operation.) (BUI 3913.)

the patient over the end of the table and placing a pillow beneath the small of the back, no difficulty is experienced in so placing the x-ray tube that rays will travel directly down the pelvic strait and show the prostate within the shadow of the pelvic girdle. Shadowgraphic pictures of the prostatic urethra may be obtained by injecting various substances into it. Stereoscopic films add greatly to the value of these x-ray studies of the prostate. The utricle and ejaculatory ducts may easily be injected with shadowgraphic material through a urethroscope and x-ray films may then demonstrate various abnormalities of the structures above the prostate, as will be discussed later. Pockets, cavities, diverticula and other abnormalities may also be disclosed in a similar way.

The subjects to be considered in this brief paper may be tabulated thus:

1. Abnormalities.
2. Injuries.
3. Inflammations.
4. Calculi.
5. Obstructions, including tumors.

A further classification under these headings will be given along with the differential diagnosis and therapeutic indications, as prescribed.

#### ABNORMALITIES OF THE PROSTATE

The development of the prostate depends greatly upon endocrine influence. In this the testicles, the hypophysis and probably also the structures in and about the third ventricle, as well as the thyroid and adrenal, play important rôles.

**Hypogonadism.**—Hypogonadism is usually accompanied by a failure of the prostate to develop normally; in fact, it is often so small as to be practically impossible to palpate with the rectal finger. In these cases the testicles, and often the penis, are small and undeveloped, and the patient has marked changes in the secondary sex characters: lack of beard and hair in other parts of the body accompanied by unusual deposits of fat, so as to give the patient a feminine figure, often accompanied by an increase in the size of the breasts, amounting at times to definite gynecomastia. More pronounced cases are generally thought to be due to changes in the pituitary and are diagnosed dystrophia adiposogenitalis. Generally, the differential diagnosis is evident. The minute differentiations, according to the different endocrine glands, which are responsible for the condition, are complex and wrapped in much obscurity.

**Therapy.**—Unless some gross pathological condition, such as tumor of the testicle, of the adrenals, pathological conditions of other endocrine glands can be found, one must depend on hormone treatment. In the present state of our knowledge, which has been so rapidly added to in recent years, it is impossible to state definitely just what glandular extracts or synthetic compounds are of most value. We have collected elsewhere<sup>1</sup> a study of hypogonadism and the changes in the

prostate which accompany it. Marked benefit has been described by some authors, but many others have had no results with endocrine therapy.

Testicular implantation has been successful in some instances, but here again we must wait for much more laboratory and surgical experience before definite progress can be reported.

**Irregular Development of the Prostate.**—This abnormality may assume various types: the absence of one or more lobes and their constituent ducts, etc. The diagnosis of these may be made by rectal and instrumental examination, but these conditions are rare, and usually found at autopsy.

The most important of the abnormalities are congenital obstructions either at the prostatovesical orifice, generally known as the vesical neck, or along the course of the prostatic urethra.

**Congenital Obstruction at the Vesical Neck.**—The differential diagnosis of these conditions depends upon the history of difficulty and frequency of urination, generally evidenced at birth, or coming on in childhood. With the advent of infection and other complications the symptoms may greatly change, infection, pyuria, irritation, pain, complete retention of urine, back pressure effects upon the ureters and kidneys, systemic effects, such as gradual onset of uremia, pyrexia, etc., all are conditions which must be considered in differential diagnosis. This is finally made by instrumental studies, which disclose the presence of obstruction at the vesical neck, visual inspection by means of the cystoscope demonstrating a bar, valve or lobule at the vesical orifice or a contracture surrounding it, the presence of residual urine, hypertrophied trigone, trabeculated and cellular bladder, impaired renal function and blood studies. These conditions must be differentiated, especially in children, from congenital valves, usually springing from the verumontanum in boys, diaphragms across the urethra lower down, hypertrophy of the verumontanum, and prostatic cysts. By means of instruments, cystoscopy, urethrograms and cystograms, the differential diagnosis can usually be made.

**Therapy.**—This is entirely surgical. The removal of the obstructing condition can usually be accompanied by trans-

urethral operations, the technic of which may either be that of the punch operation, in which the obstructing condition at the vesical orifice is caught in a fenestra, excised with an inner cutting tube, either sharp or electric. Persistent bleeding may be easily stopped by electrocoagulation, preferably with a single electrode point. The technic of these procedures is given in the surgical literature.<sup>2</sup>

**Congenital Valves.**—Those which are found in boys usually spring from the region of the verumontanum, and extend as thin folds of mucous membrane, or diaphragms, out to the urethra on each side, leaving a small aperture either circular or slitlike between the folds of mucous membrane. Congenital valves manifest themselves usually at birth, and are often accompanied by very severe uremic symptoms, associated with great dilatation of the upper urinary passages, and marked destruction of the renal cortex. In these cases a marasmic child, with distended abdomen, generally has a palpably enlarged bladder, and in many instances the kidneys and ureters can also both be palpated, and even seen through the thin abdominal wall. The urine is voided with great difficulty, and frequency, sometimes in driblets. Occasionally incontinence is present. An instrument passed into the urethra usually meets with complete obstruction about the middle of the prostatic urethra. Often every type of catheter or bougie is arrested. With the passage of a small urethroscope, one may generally see the aperture between the diaphragmatic folds and make a visual diagnosis. Sometimes a filiform can by manipulation be forced into the bladder, and the obstruction greatly dilated by followers. A cystoscope may then be introduced, and the valve seen, the dilated prostatic urethra above made out along with the trabeculated cellular bladder, and dilated ureteral orifices. If instrumental examination fails, a cysto-urethrogram may often furnish the diagnosis by demonstrating the dilated urethra above the valves, and regurgitation into the greatly enlarged ureters and renal pelves (Fig. 103). Intravenous urograms are also of great value, and show the characteristic lesions in the upper and lower urinary tract. Here again the differentiation must be made from obstructions in the outer part of the urethra, as cited above.

**Therapy.**—This is surgical. Complete removal of the val-

Fig. 103.—Autopsy specimen. Patient entered hospital in extremis. Showing congenital valves of posterior urethra, type 2. Note the dilated ureteral orifices, hydro-ureters with partial destruction of kidneys *a*, Showing enlarged view of posterior urethra and valve formation. The valves originate at the proximal end of the verumontanum, and are attached laterally to the side and anteriorly to the roof of the prostatic urethra. Note great dilatation of vesical orifice. (BUI 13248.)

vular obstruction is necessary. Sometimes this can be accomplished by the simple passage of instruments. After a filiform has been successfully introduced, large dilators may be safely passed. Without such a conductor, any attempt to pass

progressively larger sounds may be fraught with danger, as false passages have been reported with fatal ending. The use of Young's baby punch to grasp and remove the valves has been employed in many cases, especially at our clinic. Endoscopic fulguration of the valves has also been successful in many cases. We have recently collected a series of 32 cases from our clinic, and have given in detail the therapy used, and our results.<sup>1</sup> This report is accompanied by a study of the literature, which shows that whereas the condition has been known to exist for over a century, it was not until 1912, when we recognized the condition clinically and carried out an operation to relieve it, that the surgical therapy was put on a firm basis.

**Cyst of the Prostate and Its Adnexa.**—This condition furnishes interesting problems in differential diagnosis. These cysts may arise from almost any portion of the prostate, and sometimes cause marked obstruction and even complete retention. Those at the prostatic orifice may simulate lateral, median or anterior lobes. They are usually recognized by their translucency on cystoscopic examination. This is confirmed by applying a coagulating electrode, which will promptly lead to evacuation of a cyst. Aspiration has sometimes been carried out as a diagnostic procedure. The use of a cystoscopic rongeur may be helpful in diagnosis. In those cysts, which spring from the ducts in the verumontanum, shadowgraphic demonstration with the x-ray, after injecting the utricle and ejaculatory ducts, may furnish immediate diagnosis. In some of these cases the cystoscope will show an elevation of the trigone, which confirms the rounded, elastic, often fluctuant mass made out on rectal examination, generally above the prostate in the region of one of the vesicles, or between the two. When the cyst remains within the capsule of the prostate, the differential diagnosis between cyst and abscess may be difficult. If there is an orifice connecting it with the urethra, the cyst may assume the characteristics of a diverticulum, and be readily demonstrable by simple urethrogram. It may also be seen, probed or catheterized with an endoscope. By the methods above mentioned, the differential diagnosis is usually made without difficulty and the therapeutic indications readily surmised.

**Obstructive Cysts at the Vesical Orifice.**—These may be readily attacked by endoscopic and transurethral methods, as above outlined. Those of the genital ducts may be given satisfactory drainage by enlargement of the strictured utricle or ejaculatory ducts. In cases in which they cannot be reached and evacuated in this way, perineal excision may be readily carried out without entering the urinary tract.

**Congenital Enlargement of the Verumontanum.**—This is a rare condition, but may produce the typical symptoms of prostatic obstruction. A case, which has been successfully operated on, has just been described by us.<sup>1</sup> The symptomatology and cystoscopic picture may closely simulate that of a median lobe or prostatic obstruction, but the urethrogram, showing dilatation of the prostatic orifice above the enlarged verumontanum, and urethroscopy indicating that the globular mass extends down to and occupies the place of the verumontanum, make the differential diagnosis clear.

The *therapy* in these cases is surgical, and consists in transurethral resections or removal through a cystotomy, but the latter should seldom be resorted to.

**Sexual Abnormalities.**—These may best be considered here. The abnormalities are generally in physiologic functioning of the prostate and its adnexa during coitus. The most common condition is that of premature ejaculation, often caused by an enlargement, hyperemia and hypersensitiveness of the colliculus. In some cases strictures of the ejaculatory ducts, and even of the orifice of the utricle, may be important contributory factors, all of which may be recognized by the endoscopic and radiographic methods referred to above. In other cases the sexual abnormality is more extensive, involves the libido of the patient, his ability to have erections, and to consummate intercourse. These conditions are often complicated by inflammatory conditions, which must be referred to further on.

The nervous system plays a very important part, and sexual neuroses are among the most common of ailments. Not infrequently a study of these cases involves the domain of psychiatry. The differential diagnosis is clear; the treatment often complex. Much can be accomplished by local measures, such as stimulating massage through the rectum applied to the

vasa deferentia, seminal vesicles, ejaculatory ducts and lateral lobes of the prostate. This treatment should not be overdone, and should usually be gradually lessened and confined to the region of the ejaculatory ducts and verumontanum, so as to avoid removal of the fluids collected in the vesicles and ampullae, which themselves act as powerful stimulants to libido and erections. Treatment through the urethroscope, with dilators, nitrate of silver or milder antiseptics, and stimulating drugs, are of great value, but one must guard against overdoing, and combine the treatment with psychotherapy, which means getting the confidence of the patient, persuading him that his condition is not serious, that there are definite but slight pathologic conditions, which are the cause of his abnormal sexual condition, but which can eventually be removed by these simple means. If the patient can be made to cease his worrying, have confidence in the curability of his case, and be persuaded not to attempt intercourse until the libido has returned, he can often be extricated from this deplorable mental and physical condition.

### INJURIES

Injuries of the prostate are usually caused by an attending physician or nurse who, in passing sounds, catheters, cystoscopes, or other instruments, traumatize the urethra and occasionally produce false passages of greater or lesser extent and gravity. At operations upon the prostate, either transurethral, suprapubic or perineal, grave injury may result from mistaken technic. I have seen a case in which a perineal operation, by breaking through the anterior capsule of the prostate, gave entrance to infection of the prevesical space, with fatal ending. Such conditions have also followed transurethral resections and suprapubic operations. Injury of the prostate from external traumatism is rare. The solidity and strength of the prostate and surrounding capsule are sufficient to protect it. Urethral ruptures are usually at the apex of the prostate, which not infrequently is entirely severed and completely separated from the membranous urethra. It is hardly necessary to dwell upon the differential diagnosis of these conditions, which usually become self-evident after the

occurrence of the traumatism. The therapy depends upon the condition and the complications present.

### INFLAMMATIONS

**The Gonococcus.**—Gonococcus infection of the prostate has been common in the past. It has been variously estimated that in between 50 and 75 per cent of all cases of gonorrhea the prostate becomes involved. Not infrequently only the posterior urethra or ducts immediately surrounding it are invaded, and the symptoms may be so slight as to make the differential diagnosis difficult. If the secretion is only sufficient to fill the posterior urethra, and therefore does not flow back into the bladder, when the urine is voided pus from the prostatic urethra will be washed out by the first urine voided and appear only in the first glass, unless the prostatic ducts be sufficiently involved so that, in the final spasm of emptying the urine from the bladder and prostatic urethra, purulent secretion from the ducts is forced out and appears in the third glass. When the secretion is more abundant, after filling the prostatic urethra, it flows back through the internal sphincter into the bladder, and all three glasses contain cloudy urine. If the involvement of the prostate is more extensive, local pain, especially on urination, may occur, and in rare cases, this may be so severe as to produce strangury. If the swelling within the prostate becomes markedly increased, difficulty of urination, with gradually increased frequency and finally complete retention of urine (in rare cases), may occur. In such cases the diagnosis between obstructive conditions due to *other* causes must be considered. On rectal examination the prostate may show little change when the involvement is slight, but in other cases it may show definite enlargement, softening and even fluctuation when the inflammation tends to be localized. The seminal vesicles and ampullae are apt to become involved by the gonococcus, and here again the symptoms and findings vary according to the severity and extent of the inflammatory lesion. The examining finger detects changes in these structures, and indicates the progress of the disease. In acute gonococcus infections of the urethra, instrumentation is to be avoided at all cost, if possible, so that even in marked difficulty and frequency with definite evidence of obstruction,

catheterization is usually not to be done. By careful palpation and percussion of the bladder, the presence of considerable residual urine can usually be made out, and urography may also be employed to assist in the determination of prostatic obstruction. When there is fear of involvement of the kidneys, either as a result of back pressure, or by ascending infection, blood chemistry may be of diagnostic value. As the disease becomes subacute or chronic, the more rigorous diagnostic methods may be employed, including massage of the seminal vesicles and prostate, with bacteriologic study of the expressed secretion, instrumentation of the urethra, including endoscopy, cystoscopy, and sometimes probing of the ducts in the verumontanum. In acute, subacute and chronic gonorrheal prostatitis, the use of the prostatic chart is of great clinical value. As shown in Fig. 102, the areas of irregularity and induration are shown as well as adhesions and involvement of adjacent structures. Of considerable diagnostic value are referred pains in the back, hips, thighs, legs and groin, which often may be the only symptom accompanying chronic prostatitis and vesiculitis. The frequent presence of symptoms quite remote from the prostate shows the great importance of routine rectal examinations, with charting of the prostate and its adnexa, study of the secretions, microscopically and bacteriologically. These are simple procedures which may be carried out by any practitioner, and often clear up a puzzling case. When the disease is associated with sexual symptoms and neuroses, urethroscopic study of the posterior urethra and its ducts may be of great diagnostic value in these cases of chronic prostatitis. The differential diagnosis between infections of the prostate by the gonococcus and other organisms is not always easy; in fact, the common bacteria as well as tubercle bacilli may occasionally bring on acute inflammatory conditions of the prostate and its adnexa which simulate closely those of acute gonococcal infection. The differential diagnosis will depend upon the microscopic and bacteriologic study of the case as well as the other measures referred to above.

*Therapy.*—When the gonococcus invades the posterior urethra, the clinical picture is often changed at once, and in addition to the usual methods of treatment, measures directed to allay the inflammatory condition of the prostate should be

undertaken. Rest in bed, application of heat to the perineum, and through a 2-way rectal tube to the posterior surface of the prostate and vesicles have long been employed. Should very severe obstructive symptoms occur, suprapubic aspiration of the bladder can often be carried out effectively. In most cases it may not have to be repeated more than two or three times, and using a fairly small needle, no danger is incurred. A case is reported in which the bladder was aspirated successfully more than one hundred times. After one or more aspirations, as a rule, the prostatic swelling and obstruction will diminish so that natural voiding returns.

We have employed very successfully intravenous therapy. One per cent mercurochrome in doses of 12 cc. of a 1 per cent solution injected into the vein is often effective in both acute and chronic gonorrheal infections of the prostate. In a previous report<sup>3</sup> we have detailed a considerable series of cases effectively treated in this way. In the several years that have intervened since that report, we have continued to employ chemotherapy particularly in deep-seated infections of the gonococcus. Starting with 12 cc. of a 1 per cent solution, in two or three days, one may give 14 cc. of mercurochrome with impunity, and again three days later, 16 cc., and four days later, 18 cc. Five days later one may give 20 cc. It is rarely necessary to exceed 18 or 20 cc. for a single intravenous injection of mercurochrome. One of course is guided by the reaction, and the interval may be prolonged if the diarrhea is pronounced, or the patient shows symptoms of pytalism. Febrile reaction, more or less pronounced, is to be expected, and is probably an evidence of the antibody reaction by which we believe the benefit is obtained. We have in our records a considerable series of cases in which gonococci, present for a number of years, have disappeared within one or two weeks of treatment with intravenous therapy.

A further extension of chemotherapy to the treatment of gonorrhea has recently been introduced by Dees and Colston.<sup>4</sup> In their first report they recounted the striking results which had been obtained by sulfanilamide given by mouth. In a further report<sup>5</sup> they cited some 40 cases in which the remarkable effectiveness of this new form of therapy was substantiated. The most striking feature was that the posterior

urethra rarely became involved. If future experience, with a great series of cases, confirms the results already reported, it seems probable that gonococcus invasion of the prostate may be greatly minimized.

In the treatment of gonococcus infections of the prostate, both acute and chronic, we have found it desirable to give urethral injections so as to reach the organisms which lie within the canal and are not reached through the blood stream. It may be found that this should also be employed when sulfanilamide is used. Denny has demonstrated to his satisfaction that his results are superior when such is done in conjunction with the oral therapy. Both intravenous and oral chemotherapy in the treatment of gonococcus infections of the urethra, and particularly the prostate, are still in their infancy, but we feel tremendously encouraged and confidently expect that great progress will be made in combating this great scourge to humanity.

**Prostatic Infections due to Other Bacteria.**—As stated above, the symptomatology and diagnosis in many cases of acute and chronic inflammations of the prostate may be almost indistinguishable clinically from those due to the gonococci. These may be just as acute and associated with as great local, remote and urinary symptoms. When the infection is engrafted upon a previously obstructing prostate, either of the congenital or the hypertrophied types, the symptoms may be greatly exaggerated. Chills, fever and other evidences of sepsis may be present, and extension to adjacent organs may occur, rendering hospitalization and operative intervention necessary. If the process goes on to abscess formation, rupture spontaneously into the urethra or bladder may alleviate the condition, but in other cases operative intervention may be required. The therapy in prostatitis due to ordinary bacteria, as remarked above, varies greatly with the organism, the extent of involvement, the symptoms and particularly the obstructive and painful conditions that may ensue. In acute cases the methods suggested in gonorrheal involvement may be equally applicable. With the recent advent of remarkable methods of combating infections of the urinary tract and even the deep-seated urinary organs, much has been accomplished by simple means. The introduction of hexamethylamine was a great advance.

In coccus infections, our use of neosalvarsan intravenously has often been effective in sterilizing infections, not only of the urine, but of deep-seated invasions of the prostate and other organs. Ketogenic diet, along with acidification of the urine, has often accomplished wonders in sterilizing the urinary tract of infections by the colon bacillus group. Intravenous mercurochrome has been ineffective in this group, and like neosalvarsan has occasionally been very efficacious in staphylococcus and streptococcus infections. The recent introduction of sulfanilamide bids fair to revolutionize the treatment, not only of coccus infections, but also of certain bacterial infections of the urinary tract and adjacent organs. We have recently seen a case of long-standing infection of the prostate, with multiple stones present, in which complete sterilization was obtained by sulfanilamide by mouth. The infecting organism was a *Staphylococcus aureus*. *Proteus* is reported by Helmholz to be eradicable with sulfanilamide. Others have reported that it has, in some cases, also proved effective for the colon group. The whole subject is new, and much additional work must be done, but there is evidence that by means of these new methods of chemotherapy, much can now be accomplished, not only in sterilizing the urine in simple bacteriurias, but also in eradicating the organisms from the deeper glandular tissues.

When prostatitis is superimposed upon obstructive conditions it is now generally recognized that closed operations, such as transurethral resections, are rendered more dangerous, and that open surgery, especially attack through the perineum, by means of which the infection may be adequately dealt with and drainage secured, is preferable.

**Infections of the Prostate with the Tubercle Bacillus.**—Although Guyon recognized many years ago the great frequency with which the prostate was involved in urogenital tuberculosis, and was often the initial site of the infection, the profession has been slow to realize the great importance of tuberculous prostatitis and seminal vesiculitis. Surgeons have been content to remove the external evidence of the urogenital infection in the epididymis, or to content themselves with nephrectomy, when the initial lesion was in the seminal tract. In a series of papers we have verified the accuracy of Guyon's

dicta, and have urged the profession to search for tuberculous lesions in the prostate and seminal vesicles, even though there are no localizing symptoms. Walker, and the recent paper of Moore, have verified the accuracy of our conclusions. The diagnosis of tuberculous invasion of the prostate and vesicles is often difficult. The lesion may long be inoffensive and simulate on rectal examination the findings present in chronic prostatitis and seminal vesiculitis. The finding of the tubercle bacillus, after carefully excluding the smegma bacillus by the methods mentioned above, will often furnish the diagnosis. The presence of epididymitis, especially when there has been no recent attack of gonorrhea or prostatovesiculitis due to common organisms should put one on his guard. In such cases careful examination of the prostate and vesicles is essential. The discovery of induration, nodules, adhesions, enlargement not associated with prostatic hypertrophy or contractures at the vesical neck, even if the tubercle bacillus is not found in the urine or secretions, may render the differential diagnosis positive. In this one must consider prostatic calculi, especially if associated with inflammatory conditions. The x-ray will usually, by its shadows of the stones, make the diagnosis clear. Carcinoma of the prostate must always be considered and in elderly men the differential diagnosis between tuberculosis and cancer may be extremely difficult. In cancer the lesion begins in one area in the prostate and gradually spreads, whereas in tuberculosis it is often multiple in its areas of involvement, the vesicles often being the primary seat. In case of doubt, one may well expose the prostate through the perineum, as early operative removal of both tuberculous and malignant disease is generally indicated. In late cases, study of the urethra with the x-ray may demonstrate tuberculous pockets, which open into the urethra. The cystoscope and urethroscope may also reveal much of value. Study of the upper urinary passages is indicated in many cases, as it is important to determine whether a tuberculous lesion is present in one or both kidneys.

*Therapy.*—This is entirely surgical. We have proved, to our satisfaction, that in tuberculosis of the seminal tract removal of the vesicles and lateral lobes of the prostate is indicated in a large majority of the cases, with total extirpation of the vas deferens and one or both epididymes, if these are

involved. In almost one third of our cases we have discovered one kidney involved, and have removed it in addition to the radical extirpation of the seminal tract. The results obtained by these extensive surgical procedures have been very gratifying, and, in our opinion, have shown that half-way measures fail to cure the patient and are followed by an extension to other organs of the urinary tract. It is well established that renal tuberculosis should be treated by nephrectomy and partial ureterectomy as soon as a diagnosis is made; we believe equally radical measures should be applied to tuberculosis of the seminal tract, and that in addition to removal of an involved epididymis and vas, in most cases the involved seminal vesicles and prostate should be attacked through the perineum. Our recent statistics fully justify this statement.<sup>6</sup>

#### CALCULI

The diagnosis of prostatic calculi is often difficult, due to the fact that no symptoms may be produced. In the endogenous form many calculi, varying in size from a millet seed to several millimeters, are usually scattered throughout the glandular tissues of the prostate. The symptoms may be those of simple chronic prostatitis. Rarely does one encounter much pain in these cases. With the onset of infection, more pronounced changes in the prostatic gland—adhesions to adjacent structures, involvement of the vasa and seminal vesicles, extension to the epididymes, sepsis, toxemia, febrile reactions and referred pains to other parts of the body—not infrequently supervene. Sexual disturbances may also occur. When these endogenous calculi ulcerate into the urethra, or approach closer to it through dilatation of the prostatic duct in which they lie, urethral symptoms, irritation, hematuria, pain on urination and ejaculation may come on. When such a stone escapes into the prostatic urethra, definite obstructive symptoms may occur, and if it slips into the bladder, it may gradually assume proportions sufficient to give the symptoms of vesical calculus. Pain referred down the urethra and into the glans is not infrequently present in prostatic calculi, which are still in the prostatic urethra, but more frequently when they have escaped into the bladder. In a recent report of 100 cases<sup>7</sup> of prostatic calculi we found that 50 were associated with prostatitis, 29

with benign adenomata of the prostate, 6 with prostatic abscess, 2 with carcinoma, 1 was entrapped in the prostatic utricle, and 7 showed no evidence of prostatitis. In many of these cases no symptoms were produced, and the stones were discovered accidentally. In some cases symptoms of chronic prostatitis, both local and referred, were present and in fact the patient was often treated for a long time for prostatitis. In these cases on rectal examination the prostatic findings were those of a simple chronic prostatitis. The stones were not palpable, no crepitus was elicited, and in fact no areas of

Fig. 104.—Rectal chart showing large area of calculi in right lobe of prostate in patient, aged forty-six years, with history of gonorrhea twenty-one years previously, and nocturia every two hours. The calculi were not detected by cystoscope. Removal of calculi by perineal prostatectomy. Removal of small bar, but not of lateral lobes. Result: excellent. (Young in Cabot's *Modern Urology*, Lea and Febiger, Publishers.)

marked induration indicated their presence. In one case, in which the patient had been subjected to massage and local treatment for many months, an *x*-ray showed calculi in great numbers in the prostate. It seems evident therefore that it would be a good plan to take adequate *x*-rays of the pelvis in order to rule out the presence of calculi in all cases of supposed simple prostatitis. As mentioned before, these *x*-rays should be taken so that the rays are directed down the pelvic strait in order to show the shadow of the prostate well within the pelvic girdle. Shadows in that region must be differentiated from phleboliths and also from calculi in the seminal vesicles,

vasa deferentia and in the bladder itself. Calcification of Cowper's glands must also be excluded. Rectal palpation will usually assist in these differentiations by an easy recognition of the location of the indurated area (Fig. 104).

*Therapy.*—This will depend largely upon the symptoms, both local and remote. In the presence of irritating, painful and sexual symptoms, which disturb the patient greatly, eradication of the stones either by urethral instrumentation, which may sometimes be successful, or perineal operation, which is more thorough and logical, should be employed. The presence of infection adds an additional reason for proper drainage, but we have recited above a recent case in which a staphylococcus infection of the prostate, in which many stones were demonstrated by the *x*-ray, was completely eradicated by the oral administration of sulfanilamide. If chemotherapy proves to be equally successful in the future, the operative removal of nonobstructive calculi, which cause little or no symptomatology, may be discontinued.

When the calculi are associated with prostatic hypertrophy, which is fairly common, the extirpation of the stones along with the prostatic lobes by enucleation through the perineum would seem to be the method of choice. The suprapubic region has never proved effective in removing calculi in such cases, as the calculi are usually situated in the tissues between the hypertrophied lobes and the encapsulating prostatic tissue, and therefore not reached or often removed in the suprapubic operation. As one passes through the region in which these stones lie, when attacking the hypertrophied prostate through the perineum, excellent opportunity is afforded for their complete removal. When the stones have been extruded into the urethra, removal by urethrosopic or cystoscopic instruments is often easy. When they slip out into the bladder they may be crushed and evacuated.

#### OBSTRUCTION

**Purely Vesical Neck Obstruction; Contractures, Bars and Small Lobes.**—In many of these cases the disease has been present since childhood. The patients have often noticed hesitation, difficulty and frequency of urination, have not been able to complete micturition with the speed of their associates.

Compensatory hypertrophy of the trigone and the bladder muscles may for a long time provide fairly satisfactory urination, but eventually the symptoms of obstruction and irritation, and in many cases back pressure effects, are such as to lead the patient to seek relief. In these cases the prostate may often feel almost normal by rectum. There is usually some induration, particularly across the upper portion, and in the region of the median notch and furrow. Prostatitis may be present and evident in the secretion obtained by massage. Cystoscopic study showing the presence of a contracture of the vesical orifice, a bar in the median portion, or elevated lobule which obscures a portion of the trigone, which itself is usually hypertrophied and accompanied by trabeculation of the bladder, makes the diagnosis easy. With an instrument in the urethra and a finger in the rectum, the increased thickness of the median portion, and generally presence of a firm collar at the vesical neck confirm the diagnosis. Further study of the case should include the clinical and laboratory studies, which are recognized as essential in the study of prostatic obstructions generally, particularly phthalein tests and blood chemistry.

Although many operative methods were employed years ago for conditions of this type, particularly by Mercier, it was not until Bottini brought out his electrical cautery incisor that complete transurethral removal with comparative safety of these obstructions at the vesical neck was accomplished. Chetwood, with his perineal cautery prostatotomy, reported numerous successful cases. In 1909 we introduced our urethrosopic median bar excisor or punch, provided with a fenestra which entrapped the obstructing portions of the prostate, and an inner cutting tube which excised it. With this simple instrument we reported in consecutive papers hundreds of cases in which these obstructions were removed with ease and freedom from danger.<sup>8</sup> The bleeding, which occasionally was active, was found to be arrestable by cystoscopic fulguration, the electrode being applied directly to the bleeding point, and thus avoiding deep and widespread destruction of tissue. The fenestrated punch has been variously modified in instruments introduced by Braasch, Bumpus and Thompson, all of whom employed our cold cutting punch. In 1911 we had already constructed an inner cutting tube bearing an electrocautery ring, with

which the entrapped prostatic mass could be excised without hemorrhage, we hoped. As time went on we found that the use of the simple cold cutting punch and fulguration of the individual points of bleeding was more satisfactory. This method has been employed in the Braasch-Bumpus-Thompson modifications of the punch. Caulk in 1921 modified and simplified the electric cautery punch, and has been a strong advocate of its use not only in contractures, bars and lobes at the vesical orifice, but for lateral enlargements as well. To Caulk is due credit for the introduction of transurethral surgery to the universal attack upon the obstructing prostate, regardless of its size. Stern modified the fenestrated punch by introducing a cutting loop, electrified by the high frequency current, and initiated the widely used method of transurethral, high frequency, electric resection of the prostate. A further modification of McCarthy and numerous other publications have led to the great popularization of transurethral resection of the prostate which will be discussed further on.

All these procedures may be employed satisfactorily for the subject under discussion: *contractures, bars and lobules at the vesical orifice*. We believe that our simple cold cutting punch with coagulation by a single electrode of the individual bleeding points, is still the method of choice, and certainly less dangerous and equally effective.

**Adenomatous Enlargement or Hyperplasia of the Prostate.**—As stated in the preliminary discussion of the anatomy and pathology of the prostate, the lateral and median portions are the regions principally involved in the development of adenomatous spheroids which lead to obstructive conditions. As further stated, it is remarkable that the glands immediately adjacent to the urethra are those in which these adenomata occur, the lateral, posterior and anterior lobes of the prostate rarely taking part in the pathological process known as prostatic hypertrophy.

The symptoms depend upon the location of the lesion, and the mechanical disturbances produced by it. In many cases a prostatic hypertrophy may grow to considerable size without causing much obstruction, difficulty, urinary frequency or troublesome symptoms. In other cases the development of even a small lobe, particularly in the median portion pos-

teriorly beneath the vesical neck, may lead to rapid obstruction with severe concomitant symptoms. We have seen many cases in which a minute lobule caused complete retention, great dilatation of the ureters, kidney pelves, thinning of the renal cortex, and severe local and general symptoms. On the other hand, we have frequently encountered huge lobes weighing 100 Gm. or more in which micturition was disturbed very little, the residual urine slight, the impairment of the upper tract negligible. It is only by the most careful examination, using the palpating rectal finger and urethral instrumentation, cystourethrography, as well as urography, that a discovery of the actual condition present often may be made. The difficulty and frequency of urination, occasional pain and rarely hematuria are the symptoms which usually bring the patient to the doctor. Not infrequently the enlargement has already become great and residual urine and back pressure effects have produced marked changes without the patient realizing that anything serious is present. If patients could be persuaded to undergo systematic examination every year after passing the age of fifty or fifty-five, many cases of prostatic obstruction would be discovered before serious obstructive conditions have arisen. At the same time cases of early carcinoma of the prostate would be discovered. Patients should be warned that with the onset of difficulty and frequency of urination, or even hesitation and smallness of the stream, they should notify their physicians. When loss of appetite or occasional nausea, headaches and dizziness, one or all, come on, an incipient uremia may be present. One should acquaint his clientele with the importance of these symptoms, so that an early diagnosis of prostatic obstruction may be made.

Urine of low specific gravity may indicate renal impairment. The presence of bacteria, which frequently arrive without the passage of instruments, accompanied by pyuria, sometimes by fever, chills, etc., are danger signals which should lead to a careful investigation. In the study of these cases one should at once palpate and percuss the region of the bladder, after the patient has voided, to determine the presence of vesical distention and large residual urine. If such is discovered immediate catheterization is usually contraindicated (more of this further on). On rectal examination the prostate

is carefully examined for changes in size, contour and consistence. In some cases there may be little or no change, abnormality, enlargement recognizable by rectum, whereas great lobes may have forced their way through a dilated sphincter into the bladder where they can be easily recognized by the cystoscope or by urography.

If a markedly indurated area is found in the prostate, even though definite globular elastic hypertrophy is present elsewhere, one must consider the possibility of carcinoma being present, as will be discussed more fully later on. When a palpably distended bladder is made out, one should not pass a catheter unless it is possible to hospitalize the patient and undertake gradual decompression if considerable overdilatation of the bladder is discovered. Complete emptying of a greatly distended bladder through a catheter may lead to hemorrhage, a rapid drop in blood pressure, anuria, uremia and sometimes to a rapidly fatal ending. We have seen over a dozen cases in which the complete emptying of a bladder with marked residual urine was followed by a rapid exitus. (We are sorry to see that the need of this care is poohpoohed by a recent writer.)

It is needless to point out the necessity of great care to avoid infection. Not only should the penis externally be cleansed with care, but the urethra itself should be washed out so that when a sterile catheter is passed no infection will be carried in with it. One should have various types of catheters, not only the rubber or Nélaton catheter, but one with a small coudé or elbowed tip in order to ride up over median enlargements, as coudé or bi-coudé gum catheters of different size may also be required before an instrument is successfully introduced. Metal instruments, even those with an enlarged prostatic curve, may prove dangerous and should be used with care. All practitioners, who are likely to encounter cases of acute retention of urine, should be provided with the proper armamentarium, but also be sufficiently acquainted with the technic and difficulties of catheterization. Great harm can be done by careless methods, and severe complications produced, particularly on the introduction of micro-organisms. The use of the catheter, whether intermittently or inlying, to combat obstruction, residual urine, infec-

tion and other complications associated with prostatic hypertrophy is a chapter in itself, and can only be alluded to here. Suffice it to say that expert methods should be invoked early in all cases of prostatic enlargement with pronounced obstructive conditions. The development of renal function tests, particu-

Fig. 105.—Young's phthalein chart for recording appearance time and percentage output of phthalein every half hour. The lower curve in solid black lines shows the phthalein test on admission in a patient with marked obstruction to urination. Appearance time, ten minutes; output first half hour after injection, 10 per cent. Total in two hours, 25 per cent. The broken lines show the phthalein curve after continuous drainage with a catheter for six weeks. Appearance time, three minutes; output first thirty minutes, 37 per cent. Total in two hours, 65 per cent. Prostatectomy successful.

larly the phthalein test taken at half-hour intervals (Fig. 105), always through a catheter if residual urine is present, and the blood chemistry, which parallels inversely the phthalein estimations, are of great value.

*Therapy.*—In a few cases, a considerable enlargement of the prostate may require no surgical treatment. If the patient

voids freely with no increased frequency or pain, and the blood chemistry, phthalein test and cardiovascular system are negative, the patient may often be allowed to go without operation under the surveillance of his physician. Usually, however, the increase in residual urine and the development of obstructive symptoms make some therapeutic measures necessary. In rare instances prostatic massage may for a time be effective, but one must be sure that the function of the kidneys is not becoming impaired and that the cardiovascular system is not endangered by waiting. In most cases of obstruction due to adenomatous enlargement of the prostate when the symptoms are definite and progressive, operative intervention is indicated.

There is no place here to discuss in detail the procedures which may or should be employed. In our humble opinion, only when the prostatic enlargement is largely confined to the median portion posteriorly is transurethral resection preferable to prostatectomy. Transurethral resection is not generally the simple operation that many have considered it, especially in the hands of the beginner.<sup>8</sup> Its widespread usage throughout the profession has led to hundreds of unnecessary deaths. When carefully done by men who have already gained the experience necessary (often by losing a good many patients) transurethral resection may even be repeated in the larger cases several times with fairly good results. As the statistics of Alcock show, the mortality increases with the size of the prostate, and while the second and third operations may not show the mortality of the primary procedures, nevertheless they add to the sum total of fatalities. After careful consideration of the subject, we are convinced that in many cases the prostatic obstruction is of a size too great for the punch operation or methods usually called transurethral resection. In these cases exposure of the prostate through the perineum, and enucleation from within of the adenomatous masses is the safest, surest and most effective method of handling these cases. Statistics and further arguments will be found in various books on Urology.<sup>8</sup> Suffice it to say that in experienced hands the mortality is practically nil; in fact, the last four resident urologists at the Brady Urological Institute had a combined mortality in 160 cases of a little over 1 per cent, and one resident had 58 consecutive cases (which included

his very first case) without a single death. These statistics show the effectiveness of modern methods in the surgical treatment of these benign obstructive conditions.

**Carcinoma of the Prostate.**—Some twenty-five years ago we brought out the announcement which astounded many, viz., that one patient out of five who came with prostatic obstruction was suffering from carcinoma of the prostate, and that in 50 per cent of these cases hypertrophy of the lateral and median lobes was present. Further statistics soon proved our findings were correct, but not until the last two years have we known that carcinoma of the prostate is even more frequent than we had previously supposed. In independent studies of prostate specimens that came routinely to autopsy, two investigators, Rich and Moore, have found that carcinoma of the prostate was present in over 14 per cent of the cases. In 292 consecutive autopsies on males, fifty years or more of age, dying from a wide variety of causes on the medical, surgical and urological services of the Johns Hopkins Hospital during the past three years, Rich says that frank carcinoma of the prostate was found in the routine microscopic section taken at autopsy in 41 cases (14 per cent). Moore found cancer in the prostate at autopsy in 21 per cent of patients over forty-one years of age. His material was obtained from autopsies at two hospitals in Vienna in 1931 and 1932. In both instances consecutive prostate specimens were studied, and in the majority of cases no indication or suspicion of the presence of carcinoma had been present. Both investigators found that the region involved was the posterior lobe in the large percentage of the cases. Moore found that carcinoma of the prostate was three to four times as common as carcinoma in any other deep-seated organ.

Such being the case, it is incumbent upon the medical profession to try by physical examination to recognize these cases early, because we have shown that by means of the radical operation these patients can be cured without much danger or difficulty. Unfortunately, carcinoma of the prostate is symptomless and often extensive before the patient appears for medical advice. In some cases the concurrent presence of hypertrophy may bring the patient for examination fairly early. In a number of cases we have recognized the presence of

carcinoma when we discovered a small, very hard nodule in the posterior, subcapsular portion of the prostate on routine examination with a finger in the rectum (Fig. 106). If patients beyond fifty years of age could be subjected to early examination of the prostate many early cases of carcinoma would be detected. Induration of third degree, *i. e.*, very great hardness, usually accompanies carcinoma. As the lesion is generally situated beneath the posterior capsule of the prostate, it can be readily felt. An *x*-ray will exclude stone. Cystoscopy may reveal the presence of enlarged median or lateral lobes, but one should not be deceived by this evidence of benign adenomata, because as stated above, the two are frequently concomitant.

Fig. 106.—Small carcinomatous lobule in left lobe. This nodule was moderately elevated, of third degree induration. There was very little obstruction to urination. A hemiprostato-vesiculectomy was performed. The patient is well now over five years. (BUI 19552.)

When one discovers a hard nodule, which does not show a shadow with the *x*-ray, one should usually make certain that this is not carcinoma by an expert study of the case. By exposing the prostate through the perineum an excellent view is obtained, at which it is possible to palpate the suspicious region, incise it if necessary and excise a portion for biopsy. In most cases the presence of an extremely indurated area may be recognized as carcinoma, and the radical operation, which we have now carried out in over 60 cases, may be easily performed with little risk. Our statistics show that more than 50 per cent of the cases, which have been followed five years or more since leaving the hospital, have been radically cured.

Statistics from other clinics have confirmed our view that carcinoma of the prostate, if discovered sufficiently early, is an easily curable disease. The fact that the organ is surrounded by three encapsulating fasciae prevents the spread to adjacent structures for a considerable time, and therefore adds materially to the possibility of obtaining radical cures by extensive operative excision. If the medical profession could be made to realize the importance and truth of Osler's trite saying that "the difference between a good doctor and a poor one was that the good doctor knew how to make a rectal examination," and make rectal examinations a routine procedure in elderly men, many cases of carcinoma of the prostate would be detected sufficiently early for radical cure. Success in the treatment of carcinoma of the prostate depends upon the diligence and acumen of the general practitioner and the decision of operators not to relegate these patients to palliative procedures when a chance of radical cure is at hand.

## CLINIC OF DR. FRANCIS F. SCHWENTKER

SYDENHAM HOSPITAL AND THE JOHNS HOPKINS UNIVERSITY

---

### THE USE OF SULFANILAMIDE IN THE TREATMENT OF INFECTIONS

**Preface.**—The past two years have seen the introduction of a startling, new chemotherapeutic agent, sulfanilamide. Its great promise has initiated an extensive investigation of its properties but there is still a great deal to be learned. The time has come, however, when a brief summary of the existing practical knowledge of this drug should be presented to the medical profession. It should be clearly understood that what has been written in this article reflects only the relatively meager present knowledge of sulfanilamide and that further investigation may alter the opinions and conclusions presented.

**Synonyms.**—Sulfanilamide is the name given by the Council on Pharmacy and Chemistry of the American Medical Association to the compound, para-amino-benzene-sulfonamide. The drug is marketed by a number of firms under the proprietary names of prontosil, stramid, streptocide, colsulanyde, sulfamidyl and sulfonamid P.

**Historical.**—In 1935 Domagk published in Germany a report of the effect on experimental streptococcal infections in mice of an azo dye called "prontosil." The bactericidal properties of this dye for the  $\beta$  hemolytic streptococcus were so definite that its use in human infections rapidly followed. In a short time the compound was being extensively studied throughout Germany, France and later in England and the United States. It soon became apparent that the chemotherapeutic action was not a property of the whole molecule but was inherent in the para-amino-benzene-sulfonamide radical, the azo dye being without effect. It was demonstrated that

when prontosil is administered to patients or animals, the molecule is broken down by the body so that the active portion, para-amino-benzene-sulfonamide, is released from the inactive dye fraction. Since the dye itself tints the patient a vivid orange hue and is irritating to the gastro-intestinal tract, its use is rapidly being discontinued and prontosil is being replaced by sulfanilamide.

It is of interest that after the chemotherapeutic effect of para-amino-benzene-sulfonamide had been demonstrated it was recalled that the compound had been known since the latter part of the nineteenth century and as long as twenty years ago was studied for possible bactericidal effect against the pneumococcus. Apparently no one tested its activity against streptococci until it was indirectly rediscovered as described.

#### RESULTS IN VARIOUS INFECTIONS

**Beta Hemolytic Streptococcus.**—Up to the present time the greatest field for usefulness of sulfanilamide has been in infections due to the  $\beta$  hemolytic streptococcus. This includes a large number of illnesses and it may be of interest to mention a number of them specifically.

The results with *erysipelas* have been particularly satisfactory. Following instigation of treatment the patient's temperature falls rapidly to normal and the pain in the affected area is markedly reduced. The persistent spread of the lesion, so characteristic of *erysipelas*, is checked with dramatic suddenness but the eruption already present clears with only the usual speed. The results with infants, particularly newborns, in whom the mortality has always been high, are especially gratifying since the majority of these patients now recover.

*Streptococcic septicemia* carries a high mortality rate and even in those cases where recovery follows, the tendency to abscess formation usually prolongs the illness markedly. It has therefore been gratifying to find that in most cases the blood stream becomes sterile in twenty-four to forty-eight hours after the instigation of sulfanilamide therapy. The tendency to form metastatic foci is also reduced. The same good results have been seen in *streptococcic meningitis* and the rapid sterilization of the spinal fluid in a disease which has heretofore

resisted all attempts at therapy is particularly striking. In Baltimore alone there are records of 19 recoveries in 23 cases and from other cities come similar reports.

The results in *streptococcic tonsillitis* have been good but not striking, probably because the disease is usually mild and of short duration. When the infection is marked and progressive, however, sulfanilamide therapy causes a rapid decline in the severity of the disease. If treatment is begun with *peritonsillar abscess* before the lesion has broken down to fluctuancy, the condition usually retrogresses without the necessity for surgical evacuation.

The average case of *scarlet fever* is so mild that sulfanilamide causes no appreciable acceleration in the improvement rate. It must be remembered that the drug has no antitoxic property and therefore cannot be expected to replace streptococcus antitoxin in neutralizing the toxic effects of a severe infection. When, however, the focus in the throat is severe and more especially if it is progressive, sulfanilamide is indicated as an adjunct to streptococcus antitoxin; the latter to neutralize existing toxin and the former to check the infection.

Although sulfanilamide is apparently of little therapeutic value in the average acute case of scarlet fever, it has proved of definite aid in the treatment of those complications of scarlet fever which are bacterial in origin, especially *otitis media*, *mastoiditis* and *adenitis*. In fact, these conditions respond well to sulfanilamide therapy whenever they are caused by the  $\beta$  hemolytic streptococcus whether associated with scarlet fever or not.

In acute or chronic *osteomyelitis* of streptococcal origin sulfanilamide is indicated. It should be emphasized, however, that when the focus of infection is in bone, whether mastoid cells or other osseous tissue, the therapy should be continued for two weeks after a clinical cure has been accomplished. Otherwise relapses are common.

When *puerperal fever* is due to the  $\beta$  hemolytic streptococcus good results may be expected following sulfanilamide therapy.

Although the majority of infections due to the hemolytic streptococcus show rapid improvement, for some reason yet

unknown, in an occasional case sulfanilamide is without any apparent therapeutic effect.

**Streptococcus Viridans.**—Unfortunately, the results of sulfanilamide therapy with other types of streptococci have not paralleled those with the  $\beta$  hemolytic type. When used in viridans infections the drug apparently inhibits the growth of the organisms and fewer colonies are found in blood cultures but even under intensive therapy no cures have been effected.

**Pneumococcus.**—The status of sulfanilamide as a chemotherapeutic agent in pneumococcal infections is still uncertain. Experimental work has shown that the drug is at least bacteriostatic, if not bactericidal, and that its effect varies with different types of pneumococci. Best results have been obtained with type III infections. Clinically the drug has been used intensively only in pneumococcic meningitis. In these cases there is a definite prolongation of survival time with occasional recovery but the results have been nowhere nearly so good as with streptococcic meningitis. However, in a disease with such an overwhelming mortality sulfanilamide seems indicated, at least until some better form of therapy is discovered.

**Meningococcus.**—Preliminary experimental work with mice has shown that sulfanilamide affords these animals even greater protection against meningococci than against streptococci. We have treated to date 52 consecutive, unselected cases of meningococcic meningitis with sulfanilamide alone, without antiserum. The mortality in this group was 15 per cent, a figure which compares well with the 30 per cent mortality among serum-treated cases seen during the same epidemic in the same hospital. Certainly, no wide conclusions can be drawn from 52 cases but there seems little doubt that the drug is at least as effective in meningococcic meningitis as is antiserum and has none of the disadvantages due to foreign protein.

These conclusions are confirmed by experimental work which has further shown that when sulfanilamide therapy is combined with antiserum injections a synergistic effect apparently takes place. The protection of mice against meningococci by the combined treatment is far greater than one would expect from the protection afforded by each method

alone. Only further clinical trial will establish the best method of treatment.

**Gonococcus.**—The similarity of the gonococcus to the meningococcus has precipitated a trial of sulfanilamide in gonococcal infections. Because the organism is of low virulence for laboratory animals no experimental evidence exists but reported clinical trials indicate a definite value for the drug in cases of acute urethritis in the male. The results in gonorrheal ophthalmia have, in our experience, been indifferent and no data have yet been published concerning the effect in gonorrheal vaginitis.

**Bacillus Coli.**—Helmholz has recently reported excellent results in the treatment with sulfanilamide of *pyelitis* due to the colon bacillus or the staphylococcus. No therapeutic effect could be demonstrated, however, when the pyelitis was caused by *Streptococcus faecalis*. He considers the drug superior to any other urinary antiseptic.

**Bacillus Welchii.**—Recent experimental and clinical trials have produced some evidence that sulfanilamide is also helpful in the treatment of gas gangrene.

**Other Infections.**—It is manifestly impossible in the short time since the introduction of sulfanilamide to test its chemotherapeutic effect in all types of infections. At the present time one can say only that value has been proved for the drug in infections due to the  $\beta$  hemolytic streptococcus, and that favorable evidence exists with the meningococcus, the gonococcus, the gas bacillus, and the colon bacillus (at least in urinary tract infections). Results with the influenza bacillus have been disappointing. There is some experimental evidence that the drug is helpful in typhoid infections. No reports have been published on its use in infections due to protozoa, spirochetes and the filtrable viruses.

#### METHOD OF TREATMENT

Sulfanilamide is supplied in two forms, tablets (5 and 7½ grains) for oral administration and powder for parenteral injection. The powder is administered as a 1 per cent solution in physiologically normal saline and is prepared by dissolving 1 Gm. of sulfanilamide and 0.85 Gm. of sodium chloride in each 100 cc. of distilled water and warming slightly to effect

complete solution. The mixture is sterilized by autoclaving. At least one commercial company is also supplying sulfanilamide sterilized in ampules in dry form much like arsphenamine. The content of an ampule is added to the required volume of sterile normal saline and the mixture heated slightly to promote solution. No matter what method is used, the sulfanilamide tends to settle out of solution after twelve to eighteen hours. This difficulty is overcome simply by warming the mixture so that the drug is redissolved. Repeated injections of such solutions can be given subcutaneously or intraspinally without any local or systemic reaction.

The method of treatment is, with certain limits, the same for all diseases. The objective is to produce and maintain in the tissue fluids, particularly those at the site of infection, a therapeutically effective concentration of sulfanilamide. To accomplish this result two conditions must be fulfilled; first, adequate amounts of the drug must be given, and secondly, the administration must be repeated frequently enough to replace the sulfanilamide excreted by the body.

The dosage of the drug is also the same, no matter what disease is being treated, but varies according to the weight of the patient and the severity of illness. In the tabulation is given the daily dosage for patients of different age groups.

TABULATION  
SUGGESTED DOSAGE OF SULFANILAMIDE

Infection.	Total daily dosage.			
	Grams.		Number 5-grain tablets.	
	Mild.	Severe.	Mild.	Severe.
Infants —up to 40 pounds	0.9-1.5	1.8-3.0	3- 5	6-10
Children —40 to 80 pounds	2.1-2.7	4.2-5.4	7- 9	14-18
Older children—80 to 120 pounds	3.0-3.6	6.0-7.2	10-12	20-24
Adults —over 120 pounds	3 6-4.8	7.2-9.6	12-16	24-32

Daily doses are divided for intervals of four to six hours.

For ordinary mild infections such as streptococcic tonsillitis, erysipelas, pyelitis and so forth, the amount administered will vary from 0.9 Gm. per day in the infant to 4.8 Gm. in an adult. When the infection is severe enough to threaten life, such as in streptococcic septicemia or the meningitides, the daily dosage is doubled.

A general plan of treatment is to initiate the therapy by giving a full twenty-four-hour dose at once and then continue administration in fractional doses every four or six hours. For example, an older child with mild erysipelas might receive 12 5-grain tablets (3.6 Gm.) by mouth and thereafter 2 tablets every four hours. By this method a therapeutically effective concentration of sulfanilamide is produced in the blood within four hours and will be maintained at a fairly constant level as long as the treatment is continued.

The same general plan is maintained when sulfanilamide solution is injected subcutaneously except that, since it is impractical to give subcutaneous injections at four- or even eight-hour intervals, the drug is given every twelve hours. For example, an unconscious adult seriously ill with streptococcic meningitis would receive a subcutaneous injection of 960 cc. of the 1 per cent solution (9.6 Gm.) at the time of admission and 480 cc. (4.8 Gm.) every twelve hours thereafter until improvement was evident.

Intraspinal injection of the drug may be given when the infection involves the meninges. The method of administration is the same as that usually employed for injections of serum. In cases of meningitis the patient is usually treated intraspinally every twelve hours until definite improvement is seen. Thereafter, the drug is administered only by mouth or, if necessary, by subcutaneous injection. Since volumes no greater than 10 cc. to 30 cc. can safely be injected intrathecally, the spinal route must be considered only as an adjunct to oral or subcutaneous injection. In fact, since sulfanilamide is rapidly excreted into the spinal fluid, and in concentration closely approaching that in the blood, there is some question whether the intraspinal route is necessary.

The problem frequently arises as to the best route for administration. Analyses have shown that the concentration of sulfanilamide in the blood reaches as high a peak and as

quickly when the drug is given by mouth as when it is injected subcutaneously. For this reason sulfanilamide is always administered orally whenever the patient can take the pills. Only in unconscious persons, or those otherwise unable to swallow tablets, is subcutaneous injection necessary. The oral route also has the advantage that the intervals between doses are smaller and the concentration in the tissue fluids is therefore kept at a more constantly effective level. In certain cases it may be advantageous to combine oral therapy with subcutaneous injections. When this is done the same daily dosages previously recommended are followed, the amounts of sulfanilamide given by each route being added together to compute the total dose. It should be emphasized, however, that no matter by what route or routes the drug is given, the times of administration should be spaced as nearly in intervals of four or six hours as possible.

Although sulfanilamide may be given in empirical doses according to the method outlined, we have found it advantageous, at least in seriously ill patients, to control the treatment by analysis of blood and other body fluids for sulfanilamide. Marshall and his co-workers have recently described<sup>1</sup> a simple method for analysis which can be performed in any clinical laboratory. Since sulfanilamide is rapidly absorbed after administration and also rapidly excreted, it is necessary to collect specimens of blood for analysis at some fixed time after administration of the drug. A peak in the concentration of sulfanilamide in the blood usually occurs about four hours after administration. For this reason we routinely obtain a sample for analysis four hours after the first administration of sulfanilamide and again the following day four hours after any dose. From the values obtained on analysis it is possible to be assured that the sulfanilamide is being absorbed properly and furthermore to regulate the dosage in order to maintain a therapeutically effective concentration in the body fluids. For mild infections we consider a concentration of 6 mg. per 100 cc. adequate but in severe infections a level of 10 to 15 mg. per 100 cc. should be maintained.

<sup>1</sup> Jour. Amer. Med. Assoc., 108: 953, 1937.

## DISCONTINUANCE OF TREATMENT

Every case presents a new problem in determining when to discontinue treatment with sulfanilamide. As a general rule administration of the drug can be stopped when the patient has been free of symptoms and fever for two or three days. In this connection, however, one must remember that sulfanilamide itself sometimes gives rise to a febrile reaction. In cases like meningitis and septicemia where one can culture a focus of infection, treatment should be continued until the cultures on two or three consecutive days are sterile. Where bone has been involved therapy should be continued for two weeks after a clinical cure has been accomplished in order to prevent relapses. In any case it is helpful to taper off the dosage of drug over a two- or three-day period.

## MODE OF ACTION

Very little data have accumulated to explain the exact means by which sulfanilamide effects its chemotherapeutic properties. When used *in vitro* the drug inhibits the growth of susceptible organisms but it apparently has no bactericidal power on organisms already present. There is no evidence that phagocytosis is stimulated in any way. At the present time it seems probable that sulfanilamide merely inhibits multiplication of the bacteria so that the protective mechanisms of the body, such as phagocytosis, are able to deal with something less than an overwhelming number of organisms.

## TOXIC EFFECTS

The total experience thus far gained in the use of sulfanilamide is not yet sufficient to establish the exact status of its toxic effects. In the light of our present knowledge, however, it may be considered a relatively harmless drug. The average patient will show no disturbing symptoms, but in a few persons there will develop certain toxic manifestations with which the physician should be familiar. Happily none of these has as yet been serious; some can be disregarded entirely and the remainder are amenable to treatment.

**Usual Symptoms.**—Most patients who receive sulfanilamide complain of a feeling of light-headedness usually de-

scribed as "whoozy" or "drunk." Associated with this may be ringing in the ears, headache, a slight temporary loss of mental acuity and at times tingling or other paresthesias. None of these symptoms is serious and they can and must be disregarded if treatment with sulfanilamide is to be carried out. On the other hand, the frequent occurrence of these symptoms, coupled with the fact that they are considerably ameliorated when the patient is kept in bed, has given us the opinion that sulfanilamide therapy should not usually be carried out on ambulatory patients.

**Cyanosis.**—By far the commonest of the toxic manifestations is cyanosis. It develops in over half of the patients who receive the drug and varies from an almost imperceptible blueness of the mucous membranes to a deep cyanosis. From the viewpoint of the patient and his relatives it is certainly the most alarming symptom because popular knowledge connects cyanosis only with approaching death. Actually the condition appears to be quite harmless and can be ignored entirely. The mechanism of the cyanosis is not yet clear. In some cases it appears to be due to sulfhemoglobinemia but in others it may be due to the formation in the blood of some compound which imparts a blue color to the mucous membranes. There is apparently considerable variation between different patients in their reactions in this direction. Some persons develop cyanosis on very small doses of sulfanilamide and others remain free even when receiving the drug in large amounts.

**Rash.**—About 6 per cent of patients who receive sulfanilamide develop a rash, usually between the tenth and fourteenth days of therapy. The eruption is almost a replica of the measles rash and is usually accompanied by fever and malaise. It fades rapidly when the drug is discontinued and will reappear in modified form if therapy is resumed. Whenever rash develops in a person receiving sulfanilamide, treatment with the drug should be stopped. Fortunately, in most cases the eruption does not appear until late in the course of therapy, at a time when convalescence has usually begun and the treatment can safely be discontinued. In those few cases where life was threatened we have disregarded the rash and continued treatment, apparently without untoward results.

**Fever.**—Occasionally fever develops during sulfanilamide

therapy. When possible the drug should be discontinued but if necessary the fever may be ignored.

**Acidosis.**—Acidosis, in some degree, develops not infrequently in patients under sulfanilamide therapy. In most cases it is so mild as to cause no symptoms but in a few the signs of acidosis are classical. The diagnosis may be verified by demonstration of a lowered  $\text{CO}_2$  combining power for the blood. Rarely this falls to 20 volumes per cent, usually it is between 35 and 40. The acidosis is apparently due to a loss of base in the form of sodium and potassium in the urine. When the condition occurs it may be easily combated by the administration of sodium bicarbonate by mouth or sodium lactate solution parenterally. As a preventive measure sodium bicarbonate may be administered with the sulfanilamide. An adequate routine is to give 5 grains of sodium bicarbonate by mouth for every 5 grains of sulfanilamide administered up to a maximum of 10 grains at each dose.

**Acute Hemolytic Anemia.**—A rare complication we have seen is acute hemolytic anemia. For some reason not yet clear an occasional patient will show a drop in red blood cell count and hemoglobin value. This may be very rapid. In one of our patients the hemoglobin fell from 85 to 30 per cent in three days. Some patients show hemoglobin in the urine at the same time. The rapidity with which hemolytic anemia can come on makes it imperative to watch closely the erythrocyte count or hemoglobin content of the blood of all patients receiving sulfanilamide. Should the condition develop it can be checked immediately by discontinuing the drug. In severe cases or where it is necessary to continue treatment with sulfanilamide, transfusions may be used to control the hemoglobin level. No case has yet come to attention where the blood destruction was not immediately checked when the sulfanilamide administration was stopped.

**Other Toxic Effects.**—Several cases of *granulocytopenia* have occurred among patients receiving sulfanilamide. This complication is extremely rare and apparently occurs only in persons who have received the drug for several weeks. A few deaths have occurred but in the 2 cases of which we have direct knowledge improvement followed as soon as the drug was discontinued. The possibility and the seriousness of this

complication make it imperative to follow the blood leukocyte count at least every two days.

*Jaundice* has been known to occur during the course of treatment with sulfanilamide but too little is known about the exact nature to justify further discussion.

The earlier reports on prontosil therapy mentioned that albumin, a few red blood cells and casts were commonly found in specimens of urine from patients receiving the dye. We have never found this condition in cases where sulfanilamide was used. The kidneys of patients who died of their disease while receiving sulfanilamide have never shown any gross or microscopic changes which could be attributed to the drug. In fact this is true of all other organs as well. In general, however, when a definite nephritis exists it would seem better not to treat the patient with sulfanilamide especially if there is nitrogen retention. When the infection is of such serious nature that life is threatened the drug may be used even in the face of nephritis if the blood is frequently analyzed for sulfanilamide and the dosage regulated to maintain the usual effective concentration. The damaged kidney excretes sulfanilamide less rapidly than a normal organ. For this reason smaller doses of the drug will usually be necessary.

A recital of the toxic effects which may occur during treatment with sulfanilamide should be convincing evidence that the drug is not a completely harmless medication. It should not, therefore, be used indiscriminately. When the  $\beta$  hemolytic streptococcus is known to be the cause of an infection of more than mild degree, sulfanilamide is indicated. In certain cases of gonococcus, meningococcus and gas bacillus infection and in pyelitis due to *Bacillus coli* or staphylococcus the drug may be of definite value. But at the present time the evidence for its use in other infections is insufficient to justify its general clinical use, at least until further investigations have clarified the problem. Nothing will bring this promising drug into disrepute more rapidly than widespread indiscriminate use.

## CLINIC OF DR. JOHN TILDEN HOWARD

### THE JOHNS HOPKINS HOSPITAL

---

#### MEDICAL AFFECTIONS OF THE COLON

##### SIMPLE CONSTIPATION

SIMPLE constipation is a problem in the sanitary engineering of the body which I wish to discuss first. One thinks of simple constipation as either too infrequent evacuations of the bowel or as subjectively incomplete evacuations when there is no organic obstruction, no anal fissure, and no intra-abdominal inflammation to cause reflexly the constipation. All of us know persons in very good general health who have a stool only once in three or four days and, unless they complain of the condition, we leave well enough alone and say that we are not all cut according to the same pattern, though we are from the same cloth. However, under the conditions of modern life and with lay opinion as it is, the frequency of bowel evacuation should probably be at least once each day. The amount of fecal matter passed is unquestionably determined by the kind and amount of food eaten and it is my impression that, in the absence of organic obstruction or of impaction, the sensation of an insufficient stool is produced by sigmoidal or rectal spasm rather than by actual fecal retention. Simple constipation, as I see it, is not a penalty which we have to pay for the erect posture of the body; it is not related to ptosis or to redundancy of the colon; it is a penalty which we pay for our civilized social and economic system. Besides eating our excessively refined foods, we work so hard and worry so much! We work and worry not only for and about ourselves, but also for and about our children and our grandchildren.

We all know that those little barbarians, our own offspring, for the first few years of their lives have practically no constipation if they are decently fed. Mothers and nursemaids in

a mysteriously simple way train the little "animals" to open their bowels with remarkable regularity, as they train them to retain their urine until they have toilet facilities at hand. At the age of four or five these little Bushmen attend school and there they begin to appreciate the strains and repressions of our society and they may become constipated. Perhaps that unhappy day is deferred to adolescence or to the time of marriage or to a time of economic depression and worry or to the period of pain and strain of a surgical operation. Sooner or later a fair percentage of our patients (more females than males) becomes more or less constipated and asks our advice. My own experience confirms the popular medical conception that 95 per cent or more of constipation is of the spastic type; it is an expression of excessive bowel tone at some point or points and this hypertonicity is produced through the nervous system. Fatigue, irregular habits, economic worry, repressed emotions, and insufficient intake of food, all are important in upsetting the automatic function of the colon, balanced as it is between two opposing systems of control: one stimulating, the other inhibiting. The stimulator is, broadly speaking, the parasympathetic system with the vagus and sacral nerves. The sympathetic system with its splanchnic nerves is the inhibitor. It is only fair to admit that the delicate balance between sympathetic and parasympathetic systems may be upset reflexly by inflammatory processes within the abdomen and in that manner constipation may become a symptom of some other disease process. In these conditions the subordinate rôle of the constipation is usually recognized by the physician and it is treated with the remedy for the primary condition. Lane's kink, Jackson's membrane, and other conditions which produce actual organic stenosis of the bowel seem to be properly included under the heading of organic intestinal obstruction and, therefore, they are in the realm of the surgeon. Careful physical examination and a complete history usually make the separation of organic obstructions from the functional cases relatively simple. However, observation while the patient is on treatment is necessary at times and it may be very helpful in diagnosis.

**Treatment.**—The treatment of simple constipation should begin with the assumption that it is spastic and, as I have said,

the chances are 95 in 100 that the hypothesis is correct. The patient may be told (with considerable satisfaction to him) that he has an obstructive type of constipation but that the obstruction is caused by a spastic area or areas in the colon and that these spastic areas result from an imbalance in the sympathetic nervous system, that these areas are usually in the sigmoid or descending portions of the bowel and that they may have caused dilatation and atony of the right half of the colon by producing relative obstruction on the left side. When the spasm is relaxed, then tone will return to the cecum and ascending colon for the resistance in the terminal portions of the bowel will be reduced. This is a working explanation of the mechanism of the constipation and the intelligent patient will usually welcome it. When the patient understands what we are trying to do, he will be more co-operative in the elimination of irritant laxatives and enemata. Occasionally I say, "Your gastro-intestinal tube is phylogenetically one of the most primitive and elemental structures of your body. For thousands of years the ancestors of the intrinsic nerves and muscles of your intestinal tube propelled its content caudalward and, though you have been constipated for twenty, thirty, or forty years, your bad habits of spasm over two, three, or four decades haven't displaced the hereditary habits that have been established through the ages in the intrinsic nerves of the intestine itself. Could you survive decerebration, my dear patient, your intestine would function as well as that of the earthworm." This last remark is made, of course, only to selected patients. To stupid persons such explanations as I have mentioned are useless and one must dispense orders like a drill sergeant. To the intelligent, one should try to be reassuring and to get a concept of the cause of the constipation into the patient's mind. Then the battle is half won; the patient is no longer afraid of acute obstruction and serious results from his constipation.

Rest and freedom from strain are very important therapeutic measures. Frequently a camping trip or a few days at the seashore is all that is needed to give normal colonic function. Then, believing that mechanical and chemical irritation of the colon with bran, nuts, and other coarse forms of cellulose and with irritant laxatives aggravates the spasm, we put

the patient on a diet in which the cellulose content is high but in which it has been softened by cooking (the well-known smooth diet), and we stop the use of irritant cathartics and irritant enemata. We may give prunes, flake agar, or one of the newer proprietary forms of threshed psyllium seed to add soft bulk to the stools. Mineral oil by mouth and retention enemata of warm cotton seed oil are given if they seem necessary. Warm oil by rectum seems to be an excellent antispasmodic for the colon. Exercise short of fatigue is usually recommended but, except in the patient with unusually poor abdominal muscles, special calisthenics are not prescribed. Regular habits of going to stool are encouraged and sometimes a very small enema of normal salt solution or a glycerin suppository is allowed to encourage the action of the bowel at the desired time. I need only mention the glass or two of hot water before breakfast that is deservedly so popular. The after-breakfast cigar or cigaret activates some colons in a manner that I've never understood. Does tobacco really give us relaxation in our keyed-up lives at a time when our colons are ready to perform? Nicotine in small doses is said to exaggerate peristaltic contraction by stimulating the autonomic ganglia. While I don't disparage this treatment, I think that it is too unreliable to advise routinely . . . even though I do own one or two shares of American Tobacco. I have wondered why the advertising firm that promulgated "theol" of tea as an aphrodisiac has neglected its opportunities to promote the sale of tobacco by publishing its allegedly stimulating effect on the bowel.

The completely atonic colon with constipation as the result of atony does occur. In such relatively rare cases one may advise stimulation with branny foods and cascara. We are, however, very wary about the diagnosis of atonic constipation because so many colons that seem to be atonic have spasm in their sigmoidal portions with dilatation behind the spasm.

There are a certain few elderly patients who are recalcitrant to our nonirritant anticonstipation therapy. These patients have used salines for years and they expect several copious watery stools a day in spite of a rather limited low-residue dietary. They insist on large daily enemata or on

salines. One must use judgment in the management of these patients. It would be easy to reeducate their colons but most difficult to reeducate their cerebra in their ideas of bowel function. Therefore, we tolerate Epsom salt, Glauber's salt, sprudel, pluto, Hunyadi, and sal hepatica in their treatment when there is little or no subjective abdominal distress from this treatment of simple constipation. In the management of cholecystitis and a few other abdominal syndromes, the salines do have a place.

### MUCOUS COLITIS

It is only a step from constipation of the spastic type to mucous colitis or spastic colitis or irritable colon or unstable colon; they are all synonyms. From my point of view this condition is either a myxoneurosis or it, less frequently, results from irritation of the bowel with laxative drugs. Rarely it may be called "catarrhal colitis" and represents the residual of a healed ulcerative process. If mucous colitis is cured by the omission of laxatives, it may be said to have resulted from chemical irritation. If the condition follows amebic or bacillary dysentery, it may be said to be a residual from that disease. However, the majority of patients who have this affection have had no organic disease of the bowel and in them the establishment of bowel management without irritant drugs does not produce a real cure. These are congenitally frail persons in whom there has been more or less nervous strain and fear. This latter unhappy state often results from the passage of mucous casts of the bowel and the patient who sees them is certain that a portion of the lining of his gut has sloughed away. There is a diarrheal tendency in these cases and looseness often alternates with constipation as the tone of the colon varies. Gas and more or less abdominal pain (usually on the left side) accompanies the ailment. When a nervous woman complains of "gallbladder pain on the left side," one should always inquire about the occurrence of mucus in the stools and lean toward the diagnosis of irritable colon or renal disease unless evidence for gallbladder trouble, gastric ulcer, or organic disease of the colon is very strong. Because almost any abdominal condition can be simulated by an irritable colon, medical students are taught to rule out all or-

ganic conditions before making that diagnosis or the diagnosis of mucous colitis. That is a good teaching for undergraduates, lest they see an irritable colon alone in patients with acute appendicitis or with carcinoma of the colon. We, however, are probably old enough to diagnose a functional condition of the colon without having too many x-ray examinations. In fact, we must diagnose it without all laboratory tests because few of our patients can afford expensive examinations. I do want to say a word for the simple tests for occult blood on the stools of patients in whom functional colonic disorders are suspected. I am always fearful lest I miss a carcinoma in its early manifestations and a stool that is negative for occult blood to benzidine is a comforting finding in a patient who has been labeled a case of mucous colitis.

To allergy have been laid of late many of man's ailments and mucous colitis has been said to be a manifestation of sensitiveness to food or to bacteria. Some foods do seem to produce edema of the bowel and colonic spasm through an immunity mechanism but these cases are rather rare and, unless the offending food is wheat, milk, or egg, the patient who has real intestinal allergy has usually discovered his idiosyncrasy by the time that he consults his doctor. It is wise to lend a receptive ear to a patient who says that one or two foods consistently disagree with him. As everyone recognizes, the patient who claims that all foods disagree probably isn't allergic to any. We always test obscure intestinal cases for sensitiveness to wheat, milk, and egg and very occasionally valuable leads are given us. Rowe's elimination diets may be valuable in the hands of some; I have had little experience with them. Sensitiveness to colonic bacteria is a most difficult thing to prove. It has been claimed that skin-test sensitivity to a strain of bacteria isolated from the colon indicates an etiologic relationship between that organism and mucous colitis (if the patient has that condition).<sup>1</sup> Short, Dienes, and Bauer<sup>2</sup> made skin tests with strains of *Bacillus coli* and streptococci isolated from the stools of patients with chronic arthritis. They found no real contrast between the arthritic and nonarthritic patients by skin testing. Some of the intestinal strains gave uniformly stronger reactions in all persons tested than did other strains. "Variations in skin-tests may be explained,"

they said, "by differing irritability of patients' skins, natural toxicity of bacterial species, or by sensitization to certain bacterial groups." Though these workers tested arthritics and controls for skin sensitiveness to colonic bacteria, their conclusions concerning the fallacy of skin testing with colonic organisms in patients with chronic rheumatoid arthritis seems to me to apply in cases of mucous colitis. A skin reaction to a bacterial protein is not very conclusive proof of etiologic relationship unless the skin tests are adequately controlled.

**Treatment.**—The treatment of mucous colitis in our hands is moderately satisfactory. Since most of the patients who are subjects of this affection are psychoneurotics, they are improved, but rarely cured, by treatment (unless the spastic colitis has been produced by irritant cathartics). A majority of the patients who we see have previously consulted several physicians and they come to us (and, perhaps, go from us to others) with the hope that they will find someone who will confer on them a condition of perfect health. That beatific state is beyond most of the neurotics in Baltimore and I venture to say that it is so elsewhere. They have inherited and acquired nervous and psychic habits too unstable to react moderately to all stimuli and improvement is all that they can expect from medical treatment. And they can sometimes be remarkably improved! From most intelligent patients can be obtained the major cause of their functional troubles. Financial worry, strain of business, fatigue, domestic discord, disappointments, family illnesses, and thwarted ambition are but a few of the aggravating factors. Their correction or, more often, an understanding of the problem and the necessary adjustment to the unhappy situation give the most relief. Valuable adjuvants are rest, a smooth diet, retention enemata of cotton seed oil, daily doses of barium sulfate, kaolin or bismuth, belladonna and sedatives. Colonic irrigations give temporary relief but in the long run they seem to aggravate spasm. I consider acidophilus milk by mouth as a harmless method of suggestive therapy. With colonic implantations of acidophilic bacteria and with vaccines, I have little patience. Formerly it was usual to label these patients as neurotics and to dismiss them with no attempt to assist them in their distress. With rational treatment we are keeping them away from the

cults and we are doing them good. They may be neurotics, but they are usually intellectuals of a sort and to them is assigned much of the creative and cultural work of the world. There would probably be fewer irritable colons if we were all savages and lived the simple life. Still, most of us would exchange a spastic colon which could be kept quiet by treatment for the privilege of contributing a cultural bit to the world. Like our decaying teeth, the spastic colon is a penalty exacted by civilization from the more temperamental of us.

And here at the borderline of functional and organic colonic affections I must say a word about "auto-intoxication." The presence of intestinal toxemia or the probability of its presence in adult patients with organic lesions of the colonic wall is readily admitted. Whether there is such a clinical entity as "large intestinal auto-intoxication" without ulceration of the bowel is a subject that has long been debated by scientists. Certainly the idea that such a condition commonly exists has been popularized by food faddists, by salesmen of yeast, of beneficent (?) micro-organisms, of intestinal disinfectants (?), and of patent foods. To prove their point the advocates of the attractive theory of intestinal toxemia must show that toxic substances are developed in the colon, that they are developed in sufficient quantities to cause poisoning, that they are not broken down into harmless substances before they go through the intestinal wall, that they do pass through the wall, that they escape destruction in the liver, and that they will produce the symptoms of auto-intoxication when they are given subcutaneously or intravenously. As yet no such substance has met all of these requirements. My own feeling in the matter is that auto-intoxication is theoretically possible, especially when the colonic content is liquid. I believe that it is an excessively rare condition when formed or hard stools are passed; from them much absorption is unlikely. Most of the symptoms of so-called "colonic toxemia" can be relieved with surprising rapidity by mechanically evacuating the bowel (and so changing the stimulus to the sympathetic system). Dr. Alvarez<sup>3</sup> has felt that a true intoxication would not clear so quickly. As he says, "One does not immediately sober a drunken man by taking away his bottle of whiskey." We have all seen indicanuria disappear mysteriously by relief of emo-

tional tension or change of scene; there the principal rôle must have been played by the nervous system. The body's protective mechanism is a very efficient one and when we realize that we can ingest myriads of bacteria (even pure pus) and tetanus toxin and many chemicals without doing much harm, we wonder at the barriers in the enteric system. When colonic toxemia is proved in persons with normal bowel walls we shall accept it. Meanwhile we shall wonder about it and I shall be unable to explain why so many of my arthritics obtain subjective improvement from purgatives. I'm not certain that we know the whole story of colonic intoxication.

Into my office one day in September of last year came a patient who said that he was bothered with looseness of his bowels at times, particularly when he was fatigued. In November of 1935 he had gone to Puerto Rico by plane and the ship stopped over night at a small town in Cuba. There he drank water with the food served at a country hotel. About thirty-six hours later he began to have diarrhea. This continued without fever but with mucus in the stool for two months. There were mild cramping pains in his abdomen over that eight-week period and almost daily he would feel that he had to pass flatus and he would involuntarily pass a little bloody mucus onto his underwear. He wrote his family that he had acquired dysentery but he consulted no doctor about it. After the first two months he found that he was better in that he no longer soiled his clothing and he had only a very little blood and mucus in his stool. However, he did have from 3 to 6 loose movements of the bowels on most days and this condition obtained when I saw him. His physical examination revealed nothing remarkable; he had lost no weight. His stool was mushy and it contained a moderate amount of mucus and some flecks of blood. No motile amebae or cysts were found in it. Through the sigmoidoscope the rectal mucosa was hyperemic and edematous and it bled very easily when it was touched lightly with the tip of the instrument. Stool cultures showed *Bacillus dysenteriae* of the Flexner type. The blood serum in high titer agglutinated the Flexner bacilli. The diagnosis was clearly chronic bacillary dysentery and this case introduces us to the field of the ulcerative colitides.

## ULCERATIVE COLITIS

It is our custom to examine all patients who have bowel symptoms with the sigmoidoscope. We want to know the appearance of the colonic mucosa in patients with diarrhea and we note the state of the hemorrhoidal veins in constipated persons. In our hands sigmoidoscopy is a thoroughly medical procedure. No operating room or aseptic technic is required and any internist with a gentle hand is qualified to examine the lower 12 inches of the colon through an endoscope. The mucosa of the normal bowel is easily recognized; it resembles the lining of the cheek. In the first stage of ulcerative colitis the mucosa is hyperemic and friable and superficial ulceration may be present. I do believe that at times in the mucous colitis that I have called neurogenic, particularly when it is of long standing, one may see a hyperemic and edematous mucosa, the patient may have a temperature of  $99^{\circ}$  to  $99.6^{\circ}$  F., and a few leukocytes may be found in the colonic exudate. This may be called "catarrhal colitis" and it seems possible that the normal bacterial inhabitants of the colon have acquired some virulence or, more likely, that the resistance of the intestinal wall may have been lowered (perhaps by local treatment). In these cases I tend to hold to the fundamental neurogenic etiology unless they are proved to be specific and, though I may be stubborn, I think that the infection is superimposed on a spastic colon. In the second stage of ulceration the lesions are better defined and the mucosa between the ulcers is thickened and is very friable. The ulcers may be pin-point in size or they may be larger. Frequently the bleeding so clouds the field that we remark that the colon resembles a section of raw beef. In the third stage the ulcerations have reached the submucosa and they are very deep. Tufts of hypertrophic mucosa are between them. I cannot tell from the gross appearance of the ulcers the difference between those of amebic dysentery, bacillary dysentery, and nonspecific ulcerative colitis. Sometime when you are in Washington and after you have visited the public buildings, called on your congressman, seen the recent acquisitions at the Corcoran and the Smithsonian, visit the Army Medical Museum that is adjacent to the Smithsonian. There are displayed excellent specimens of ulcerated colons.

Whenever the endoscopic picture suggests that we are looking at an ulcerative lesion or when there is a long history of chronic diarrhea, we obtain through the sigmoidoscope specimens of stool and of exudate for immediate microscopic examination. The diagnosis of amebic dysentery is usually so very simple that it is ruled out first. In cases with active diarrhea and bowel ulceration the vegetative forms of amebae are quite easily found in the mucous exudate. When colitis is present and trichomonads are found in the stools, one should search especially carefully for amebae. A warm stage is not necessary for the recognition of these protozoa if the material has been obtained through the sigmoidoscope in an adjoining room or if it has been selected from stools passed at the laboratory. I am not enough of a parasitologist to be certain of my differentiation between *Endamoeba histolytica*, *E. coli*, *E. nana*, etc. If there is colitis and amebae are found, I presume that they are of etiologic significance until antiamebic treatment fails to relieve the symptoms. Occasionally I send the stools to the parasitologists in the Johns Hopkins School of Hygiene; with their greater acquaintance with protozoa, they sometimes pick up parasites which I have missed. When the patient is having formed stools, vegetative forms of amebae are less easily found and a search for encysted forms is made. This is not difficult and we use the method of Craig.<sup>4</sup> A bit of stool the size of a pea is emulsified with water or with normal salt solution in a test tube and this is strained through 2 layers of cheesecloth into a centrifuge tube. The tube is filled with water or with salt solution and centrifugalized at moderate speed for a few minutes. A drop of the sediment is placed on a slide and a drop of 2 per cent iodine solution is mixed with it. After about three minutes the specimen is examined with the high-power objective on the microscopic stage. Cysts of *E. histolytica* appear as lemon-yellow disks about the size of the ordinary leukocyte (or perhaps a little larger) that one sees in the urine. The nuclei and the karyosome stand out as refractile bodies. The cysts may contain 1, 2, 3 or 4 nuclei if they are of the *histolytica* variety. Paulson of Baltimore usually cultures the exudate or stool on a special medium made of human serum, rice flour, and liver infusion agar and frequently after three or four days amebae can be cultivated.

We do not do this routinely, however, and we are content with the simple microscopic examination of the stool to rule out diarrhea of protozoan etiology. Complement fixation tests for the detection of amebic infection have been devised by Craig and others. These are still in the experimental stage and in Baltimore they have been quite unreliable. Paulson has sent approximately 20 sera to Dr. Arnold of the Department of Pathology of the University of Illinois for a complement fixation test with the latter's technic. The specimens were numbered and Paulson has told me that Arnold selected the patients who harbored *E. histolytica* with considerable accuracy.

If no amebae are found, cultures of the stools are made for the typhoid-dysentery group of organisms. If suspicious colonies are found, they are worked out for us by the bacteriologists. Agglutination tests are also run with the patient's serum on the Sonne, Shiga, and Flexner (W and Z) strains of dysentery organisms. Frequently the dysentery bacillus cannot be grown but the serum from the patient in high titer will agglutinate a certain strain of bacilli. When this occurs, it is presumed that the ulcerative colitis is a dysentery.

When there is colonic ulceration, when no amebae are to be found, when there is no evidence of bacillary dysentery, when a Frei test (which I will mention again later) is negative, and when there is a history of insidious onset, we diagnose nonspecific ulcerative colitis. This is variously termed "colitis gravis," "idiopathic ulcerative colitis," and "suppurative colitis."

I believe the etiology of idiopathic ulcerative colitis to be still unknown. Workers in England have felt that it was an aberrant form of bacillary dysentery. Virulent strains of *Bacillus coli* have been accused of producing it; so have *B. proteus*, *B. mucosus capsulatus*, and others. In 1924 and 1925 Dr. Bagen,<sup>5</sup> working under Rosenow in the Mayo Clinic, presented what he considered to be evidence in support of his belief that a diplococcus was the specific cause of the disease. In his first 2 papers he reported that 75 strains of diplococci had been isolated by him from cases of ulcerative colitis, but only 25 of these had been studied culturally. The others had been identified morphologically (a most unreliable way to identify a diplococcus isolated from the intestinal tract), or by

agglutinations (an especially unreliable manner where streptococci and enterococci are concerned because many of them agglutinate spontaneously). In 1927 Dr. Bargaen<sup>6</sup> reported that he had isolated the organism in 189 of 266 cases and 105 strains had been studied culturally. In 1924 and 1925 Dr. Bargaen said that his bacterium was an  $\alpha$ -zoned diplococcus and that it never fermented inulin and mannite. In 1927 he said, "Of 105 strains tested, 41 fermented mannite and 64 did not." In 1930 he reported that his diplococcus "does not usually ferment mannite but lacks the power to ferment inulin." Dr. Bargaen said that his organism was heat resistant. He sent a typical strain to Torrey of Cornell and there it was not heat resistant. This conflicting evidence suggests to any critical observer that more than one type of coccus was dealt with. Dr. Bargaen injected his diplococci into rabbits and reported that many of them showed colonic ulcerations following these injections. He reported as controls the work of Rosenow and others who worked independently of Bargaen on different problems and they did not use other organisms isolated from the colons of patients with ulcerative colitis. Workers at the Mayo Clinic were impressed by Bargaen's experiments and sera were prepared and vaccines made. These preparations became the basis for the treatment of idiopathic ulcerative colitis at Rochester. The clinical results were considered to be quite satisfactory and the number of ileostomies done there annually was markedly lowered.

In 1926 and 1927 Paulson<sup>7</sup> of Baltimore made a study of the bacteriology of the colon in patients with ulcerative colitis. He studied 14 cases. From 13 of them he isolated 10 types of streptococci—including Bargaen's diplococcus (Bargaen's original criteria were applied in the classification). From the fourteenth case he could isolate only *Bacillus coli*. No one type of streptococcus was found to be present in more than 3 cases and Bargaen's organism was isolated in 2 cases. Paulson injected 7 of the 10 types of streptococci (including in this 7 the 2 strains of Bargaen's organism) into the venous system of rabbits. Five of the strains (again including Bargaen's diplococcus) produced primary inflammatory changes in the colon of 45 per cent of the animals injected. Paulson found that 2 types of living streptococci and a killed  $\beta$  hemolytic

streptococcus isolated from cases who did not have ulcerative colitis gave lesions when injected intravenously which were similar to those produced by Bargaen's organism and the streptococci from ulcerated colons. A living strain of *B. coli* from a case of amebic dysentery gave ulceration of the colon. This evidence seemed to show that Bargaen's organism was not specific in the etiology of idiopathic ulcerative colitis. Paulson studied the flora of the human ileum. He found that gram-positive cocci were normal inhabitants there and he learned that Garrod had found that by giving laxatives to normal persons he could increase tremendously the number of cocci in the stool. Ergo, anyone with a diarrhea is entitled to show diplococci or streptococci in the feces. They are simply washed down from the small intestine. Paulson noted, as had Hurst, that in the bloody culture medium of an ulcerative colitis the growth of cocci is encouraged. Therefore, these organisms are increased in the stools of the patients who have nonspecific ulcerative colitis but they are not the primary etiologic factor.

The theory that ulcerative colitis is due to a vitamin deficiency is certainly not proved and I regret to say that I have nothing constructive to contribute toward the search for its true cause.

**Treatment.**—The treatment of amebic colitis is quite simple and it may be readily obtained from the textbooks. To the average case we give emetine, carbarsone and chiniofon (yatren) simultaneously. Emetine gives almost immediate relief from symptoms but, unfortunately, it does not attack the encysted forms of the parasite. We give it as emetine hydrochloride in doses of 64 mg. daily for from seven to ten days. Of course it is given hypodermically. Rarely the emetine will aggravate the colitis by its excretion through the bowel. Then the dosage is reduced or it is given up entirely in the cases which seem to have an idiosyncrasy for it. Carbarsone is probably our most valuable therapeutic agent in amebic colitis. It is given in doses of 0.5 Gm. daily for ten days. We also give 2 Gm. of chiniofon in 200 cc. of water every other day as a retention enema. On the alternate days an 0.5-Gm. capsule of the same drug is given twice a day. With this triple attack we feel that the patient has the maximum opportunity to be rid of his parasites. After ten days of treatment the

patient is dismissed for three or four weeks and, if the parasites are found in the stools at the end of that period, the treatment is repeated.

Acute bacillary dysentery is usually a self-limited disease. The chronic form is quite intractable and rarely is the so-called "specific serum" specific. It may be tried, however, together with the general measures for the treatment of idiopathic ulcerative colitis which I shall mention or with any others which may prove effective in your hands.

In the treatment of nonspecific ulcerative colitis two things are in our favor: the disease has spontaneous remissions and we can always have the surgeons come to our rescue with an ileostomy. It is my present belief that ileostomy should be deferred as long as we dare defer it and, perhaps, a little longer. If we can just get the patient to hold out with us long enough, a remission is very likely to come. I don't mean that ileostomy should be postponed until the patient is in extremis. However, it should be withheld until we are driven to it by a persistence of local and general symptoms in the face of all medical measures. A complicating arthritis or other metastatic infection, marked undernutrition, and sometimes chronicity of symptoms are indications for ileostomy. The principles of the medical treatment of these patients are very like those of the treatment of tuberculosis or of any chronic infection: the patients should be generally built up. Forced feeding of a soft or smooth diet with quantities of vitamin-containing foods, cod liver oil, rest, sunshine, an equable climate, *i. e.*, Florida or the Gulf States in the winter, are the general measures. Several times I have seen remissions produced by the intramuscular injection of increasing doses of horse serum. Perhaps Barger's serum acts as a nonspecific protein and so does good. Rarely are irrigations and enemata necessary. When they are used, I prefer tannic acid in warm water. Bismuth by mouth is comforting and helpful. Vaccines have never impressed me with their usefulness in this condition, though they may be tried. Transfusions may be necessary and they often help the patient to get into a remission. In England anti-dysenteric serum is given intravenously. If it does good, I think that it is because it is foreign protein. At this time I know of no single measure so helpful to the patients as the

general up-building program. Remissions may last for months or years and between them the patients may be symptom-free, though the sigmoidoscopic picture may be that of an edematous friable bowel mucosa.

### LYMPHOPATHIA VENEREA

Ten or twelve years ago I was taught that all strictures of the rectum that were not carcinomatous and that had not followed rectal surgery were of syphilitic etiology. Later my pathologist friends told me that syphilis of the rectum (other than chancre or the mucous patches of the secondary stage) had never been proved. Then I heard that tuberculosis and gonorrhea were etiologic possibilities in this condition. I am still told that these conditions do produce rectal stricture but I have never seen strictures that could be definitely attributed to them. The pathologic reports on excised bits of stricture have uniformly read "chronic inflammatory tissue." In the past seven or eight years considerable evidence has been produced to show that probably the commonest cause of noncarcinomatous stricture of the lower rectum is lymphopathia venerea. This is also called lymphogranuloma inguinale, climatic bubo, or the sixth venereal disease. This is an interesting entity and I wish to consider it only in its relationship to colonic conditions. This disease is caused by a filterable virus and it differs from simple granuloma inguinale in its clinical manifestations, in its failure to show Leishman-Donovan bodies, and in its lack of response to antimony therapy.

Formerly lymphopathia venerea was considered to be a tropical disease, though its venereal mode of transmission was recognized. It now seems to be quite widely disseminated and to be most frequently found in peoples who are sexually somewhat promiscuous. The colored races, therefore, seem to be quite susceptible.

The virus of the disease has a predilection for the lymphatic system and, whether it produces inguinal buboes or rectal stricture, depends on its path in the lymphatics. In the male a small herpetiform lesion appears on the penis from ten to twenty days after exposure; it is considered to be inconse-

quential and it soon disappears. In two or three weeks there is swelling of the inguinal glands on one or both sides and suppuration of them is very common. The lymphatic inflammation may persist for a very long time. This is usually the extent of clinical manifestations in the male and in him rectal stricture is relatively rare. In the female similar buboes may occur if the primary lesion is on the vulva. However, the primary sore is usually on the cervix or in the upper vagina and, because the lymphatic drainage of these parts is into the anorectal glands rather than into the inguinals, there is involvement of the perirectal lymphatics with chronic inflammation or a granuloma and, as fibrous tissue forms, there is a gradual stenosis of the rectum. As one recalls his cases of benign rectal stricture, he remembers that by far the greater number of them was in females. It is said that rectal stricture from this disease is produced in males only by direct inoculation of the virus into the rectum, *i. e.*, by sodomy. My own opinion of the few male patients in whom I have seen benign rectal strictures makes me believe that this conception of the mode of infection of the rectum in males is probably correct.

In 1925 Frei reported that an antigen for diagnostic skin testing could be obtained by aspirating pus from a bubo of a patient with the disease. The pus is diluted and heated and is injected intradermally in persons suspected of the disease. In the positive cases a local reaction similar to the tuberculin reaction is obtained after forty-eight hours. The area of redness should be at least 0.5 cm. in diameter. It is dissimilar to the tuberculin reaction in the small area of necrosis of the skin at the center of the reaction. Virus which has been grown on artificial media may also be used for the test. Most workers with the test of Frei believe it to be practically specific for the infection. It is with this test that most cases of lymphogranuloma inguinale and rectal strictures caused by that disease are diagnosed. The test is positive for many years after the primary inoculation.

It has been my experience that most of the patients with nonmalignant rectal stricture have had rectal ulceration and diarrhea. Others have noted the ulceration above the stricture and they have discussed the cause of this. Some have felt

that the ulceration was due to the virus and others have felt that it was caused by fecal stasis. Recently the virus has been isolated from ulcerated colons above the strictures and positive Frei tests have been secured with that virus in known cases of lymphopathia venerea. The disease has been reproduced by the inoculation of virus obtained from an ulcerated bowel into the penis of a man who later gave a positive Frei test. Goodman<sup>8</sup> of the Section on Syphilis at the Johns Hopkins Hospital reported positive Frei tests in 7 patients from a series of 20 unselected cases of ulcerative proctitis and colitis without rectal strictures. He feels that lymphopathia venerea should be considered in the differential diagnosis of all cases of ulcerative colitis. Certainly it may produce a proctitis and Goodman believes that he has seen it produce ulceration of the entire colon and of the lower ileum.

**Treatment.**—The treatment of lymphopathia venerea is most unsatisfactory. Antimony does no good and we have left only the general measures used in nonspecific ulcerative colitis. Time is sometimes kind to these patients and in those with persistent trouble and marked rectal stricture we advise colostomy.

In the medical treatment of colonic conditions, especially in the treatment of the chronic ones, the well-known art of medical practice is invaluable. First, it keeps the patient sticking to the principles of his treatment by means of encouragement and hope; and, in the second place, it lends the ever necessary patience and the always helpful "will to get well."

## CLINIC OF DR. W. S. TILLET

### THE JOHNS HOPKINS HOSPITAL

---

#### THE SERUM TREATMENT OF PNEUMONIA

THE increasing use of type-specific antipneumococcus serum in the treatment of pneumonia indicates the growing recognition of its value as a therapeutic measure. In the past, a number of accessory factors pertaining to its practical use have retarded its general adoption by physicians even though large clinics have, for several years, found the treatment to be of definite value. At the present time, the continued simplification of procedures, both in the laboratory and at the bedside, is eliminating difficulties to such an extent that the successful administration of serum treatment is becoming increasingly more feasible. I should like to discuss certain points concerning serum treatment of pneumonia and to emphasize particularly the problems that need to be taken into consideration when apparently unsatisfactory results are obtained.

A large volume of literature has accumulated on the subject of serum therapy in pneumonia since the monograph of Avery, Chickering, Cole, and Dochez<sup>1</sup> appeared in 1917. Without reviewing in detail these reports, experience so far has shown that cases of type I pneumococcus pneumonia treated with the homologous antipneumococcus serum respond most satisfactorily. However, with a growing understanding of the immunologic background on which serum treatment is based, wider application may be reasonably expected. In addition to type I pneumococcus infections, 5 of the other specific types—II, V, VII, VIII, and XIV—have, up to the present time, been reported as being favorably influenced by appropriate specific anti-sera. The principles underlying treatment and the problems which may arise during treatment appear to be essentially

the same, regardless of the particular type of pneumococcus causing the infection. Consequently, this discussion is generally applicable, although only the treatment of type I pneumococcus pneumonia is taken up in detail.

In the administration of serum it is generally agreed that there are 3 requisites which promote the most favorable results. They are as follows:

**1. Treatment Begins within the First Twenty-four to Forty-eight Hours after Onset.**—Cecil<sup>2</sup> has recently summarized the results of early treatment and shows that in type I pneumococcus pneumonia the mortality of cases treated in first twenty-four hours of the disease is approximately 5 per cent, a mortality rate which he estimates to be about one sixth of the usual expectancy in cases not treated with serum.

In order to take advantage of the important factor of time, rapid determination of type of pneumococcus causing infection is necessary. Fortunately, the so-called "Quellungsreaktion," by which typing may be done on satisfactory specimens of sputum directly and within a few minutes, permits the laboratory to fulfil its duty with considerable accuracy and speed. The typing phenomenon consists of a swelling of the capsule on the pneumococci in the presence of homologous type-specific antibodies. It was first noted by Neufeld,<sup>3</sup> was more recently described by English investigators,<sup>4, 5</sup> and is well described in American literature.<sup>6, 7</sup> Experience of the past few years has shown that the test is a practical measure which is being generally adopted and that its use greatly increases the opportunity for physicians to begin treatment within a few hours or less of the time sputum is delivered to the laboratory for examination. The first condition, therefore, for best therapeutic results receives valuable aid from these more recent laboratory developments.

**2. The Amount of Serum per Dose Should be Adequate.**—The answer to this question cannot be given categorically but the experience of different clinics indicates fairly definitely the amounts which appear to be necessary. The removal of antibodies from whole serum and their concentration in small total quantities of fluid has facilitated greatly practical administration. The adoption of a unit for measurement of protective power of sera has also contributed to

standardizing dosage, which is regularly expressed in units per dose. The average initial dose is from 20,000 to 60,000 units at the Johns Hopkins Hospital, usually being 40,000. One may be guided to some extent by the severity of the case when first seen, the larger doses going to those patients who appear to be severely ill and who may have a septicemia. As a general rule, it is perhaps desirable to lean to the side of the larger dosage since adequate amounts are of great importance and since the liability to reaction is not seriously increased.

### 3. The Repetition of Injections is Also Important.—

As the serum treatment of pneumonia has been improved it is interesting to note that the interval of time between treatments has been continually shortened. At the present time the opinion seems to prevail that the second treatment should be given not longer than four hours after the first; even two hours is preferable, providing the immediate reaction of the patient—if any has occurred—to the first injection has not been unusually marked, and has subsided. The dosage for the second treatment may be 20,000 to 40,000 units, preferably the latter. A third treatment is usually desirable, using the same interval and the same dosage as in the second injection. Following this régime it may be seen that in from four to eight hours after beginning treatment, patients will have received from 60,000 to 120,000 units.

In patients treated early in the disease and in the manner described it is the rule to see great improvement and even recovery in twenty-four to forty-eight hours; whether or not additional treatment is indicated depends on the individual case. In severe illnesses with septicemia continuation of intensive treatment is indicated and the results often justify the efforts.

Several methods have been devised as guides to both dosage and duration of serum treatment. One of these consists of testing samples of serum from the patient at intervals for the presence of excess circulating antibodies. Another method consists of skin tests with the type-specific polysaccharides. A positive test occurs as a wheal in fifteen to thirty minutes and is intimately associated with a favorable prognosis. For details concerning these procedures, you may refer to detailed reports in the literature.<sup>2, 7</sup>

It is not possible at this time to discuss in detail all the measures which come up for consideration in serum treatment. Brief mention may be made, however, of the following: (a) test before injections, for patient's possible sensitivity to serum; (b) slow introduction of serum, particularly the initial injection; (c) dilution (1-5 times) of serum with physiologic salt solution if patient is desperately ill or if unusual reaction may be suspected from history of patient.

It should also be emphasized that although best results are obtained with patients treated early, favorable results are also obtained in cases treated later in the disease. Although statistical evidence in large series may not give striking proof of the value of serum in patients treated late after onset, there are a sufficient number of individual instances, in which patients severely ill after several days of pneumonia were definitely benefited by serum. Its use should therefore be seriously considered in any case with well-marked active infection regardless of the time in the course of the disease at which the patient first comes under observations.

Of particular interest are patients, not infrequently encountered, who do not respond satisfactorily, even though the serum therapy was properly administered. The patient to be described will serve as a basis for a discussion of some of the reasons for unsuccessful serum results.

Patient B. F., thirty-one-year-old housewife, was admitted on the third day after cough and fever had developed, following a "cold" of ten days' duration. She did not at first appear acutely toxic although respirations were rapid and labored. She presented classical signs of consolidation of left lower lobe. Correct typing was unfortunately not obtained for eighteen hours. It finally proved to be type I pneumococcus. Blood culture was positive, with 38 colonies per cubic centimeter. White blood corpuscles 12,200 per cubic centimeter at time of admission. She received a total of 220,000 units of type I antipneumococcus serum in approximately thirty hours. A second blood culture taken on day following beginning of treatment was sterile. On the day after admission there was evidence of spread of the lesion and x-ray suggested fluid at left base. Attempts to find fluid by thoracentesis were not successful. Patient died six days after admission on ninth day of disease. At autopsy pneumonia was present and also encapsulated empyemata on both sides close to mediastinum.

In this patient it is difficult to assess the importance of the pleural infection *per se* since she had considerable general in-

fection at the time of admission. Through vigorous serum treatment it was possible to sterilize the blood stream but the severity of the infection from all points of view was too great to be overcome. The course of this patient serves, however, to illustrate the fact that complications of pneumonia, such as empyema, may appear which confuse the picture. Because empyema is relatively so common in pneumonia, its possible presence should be suspected *first* in patients who ought to respond to treatment but who remain acutely ill. In other patients whose condition may be complicated by empyema the pleural infection may appear later in the course of the pneumonia than in the patient just described, and as a result prolong the illness beyond the time of expected recovery. If the pus in the pleural cavity is located next to the thoracic wall instead of adjacent to the mediastinum the condition is not difficult to diagnose or treat successfully by appropriate drainage. While considering the subject of empyema, it is also important to bear in mind that this complication is more likely to occur in patients with type I pneumonia than in the other types, whether serum treatment is used or not.

Other complications, which require special measures and are not combated successfully by serum alone, may also intervene. They may be part of the pneumococcus infection itself, as, for example, meningitis or pericarditis. They may be dependent upon a superimposed complication due to some other organism, such as streptococcus or staphylococcus. Several other complicating manifestations might be mentioned, such as lung abscess or phlebitis. However, it is easy to see, from those described, how important it is to assay carefully the possible causes for continuation of acute illness in patients who receive serum.

There are other conditioning factors which should be given consideration when serum therapy is ineffective. For example, a mistake in typing may be made by the laboratory. This error is part of the human equation and inevitably occurs. When, therefore, in the absence of demonstrable complications and in spite of adequate treatment, the course of the disease is not influenced, a careful recheck of sputum typing should be requested.

Analyzing further the instances of poor results, the failure

of serum to be helpful may be accounted for by imperfections in the patients' reaction to the infection. For example, a leukopenia may be present. Since the mechanism of the curative action of serum is opsonization of the organisms, phagocytosis is necessary to complete the eradication of the pneumococci. Insufficient numbers of leukocytes may therefore delay the process. When this occurs, blood transfusions are sometimes helpful.

In still other patients, the failure of some element of their own mechanism of defense seems to occur, but no method of measuring the deficiency has, as yet, been devised. Because of our ignorance in this respect, no forms of supportive treatment have been found to be uniformly helpful. The need for additional study in this group of patients is obvious.

With respect to the treatment of pneumonia due to types of pneumococci other than type I—namely II, V, VII, VIII, and XIV—experience with type II has been the largest. The results have been less impressive than those obtained in type I cases. However, they indicate that if treatment is started early and if dosage of serum is large, perhaps 40,000 to 80,000 units per dose and with an average total of 150,000 to 200,000 units, the results are definitely favorable. Bullowa,<sup>8</sup> Finland and Tilghman and their associates,<sup>9</sup> have presented their results concerning types V and VII. From their reports, as well as from the limited experience here, the outlook is promising that these types of infection may be benefited by homologous type-specific serum and that their regular use is indicated. Bullowa has also related his experience with serum in the treatment of cases of type VIII pneumococcus pneumonia,<sup>10</sup> and also of type XIV.<sup>11</sup> He reports favorable results in both instances. Viewing the continuing development of the serum treatment of pneumonia it seems likely that as the immunologic background is more completely understood the application of the principles to patients will become more useful and more practical.

## CLINIC OF DR. MOSES PAULSON

### THE JOHNS HOPKINS HOSPITAL

---

#### NEWER ASPECTS OF GALLBLADDER DISEASE OF PRACTICAL IMPORT

*The Problem—Physiology and Pathologic Physiology of the Extrahepatic Biliary System—Differential Diagnoses and Methods—Final Disposition: Selection of Cases for Surgical Intervention and for Medical Management—Medical Management: Dieto-Pharmaco and Psychotherapies*

**The Problem.**—Gallbladder operations frequently do not give the anticipated relief from symptoms for which they were performed. For years, some internists, like my Chief, Thomas R. Brown, and my colleague, John Tilden Howard, have made such a claim to which little attention was paid. Of late, first-rate surgical clinics are reporting that about 33 $\frac{1}{3}$  to 43 per cent of those so submitted have felt that little or no benefit was derived therefrom. Thus, it becomes desirable to examine the several practical considerations toward facilitating and improving diagnosis and toward a more critical selection of cases both for medical and for surgical therapy.

In most situations, the principle holds that disease should be attacked early to secure the best therapeutic results. This was suggested for cholecystitis by Alvarez in 1923. However, today there is reason to believe that this principle does not hold in biliary tract disease. For instance, when comparisons are made of the results of gallbladder surgery in cases with minimal changes to those in whom the changes were more advanced, the inescapable conclusion—from a statistical standpoint—is that cholecystectomy should not be undertaken in early cases before marked changes occur. This is not to be carried to its logical conclusion; the problem is not quite so simple, since too long-standing involvements result in irreparable damage to the liver, pancreas and extrahepatic bile ducts.

Thus, to the family practitioner to whom the vast majority of these cases come for diagnosis and relief, and into whose hands is placed their disposition, the following questions must arise in instances where gallbladder disease is suspected.

1. How much does the gallbladder contribute to the patient's complaints?

2. How shall the diagnosis be established?

3. What cases shall be treated medically?

4. Who shall be submitted to surgery?

5. What shall be the procedure in the face of recurring preoperative or new postoperative symptoms; what are their causes and what is to be done for them?

**Applied Physiology of the Extrahepatic Biliary Tract.**—A step toward answering these questions will be taken upon the pointing out of the few known practical facts of extrahepatic biliary tract function. The gallbladder, like the intestine, manifests three types of activity: (1) absorption, (2) secretion, and (3) motor activity.

1. *Absorption.*—Hepatic bile is concentrated in the normal gallbladder four to ten times and is slightly acidified on reaching the unimpaired viscus, thus rendering fats and cholesterol soluble. An acutely inflamed mucosa will not concentrate bile. If such inflammation is patchy, it may do so to a varying extent. Degrees of partial bile concentration also occur when only the muscularis or serosa is involved. Upon recovery, if there is not too much replacement by fibrosis, the organ may again adequately concentrate. The gallbladder mucosa may become hypertrophied, either because of long-standing disturbances of duodenal motility or a hypertonic sphincter of Oddi. Nevertheless, concentration occurs here. Papillomata seem not to influence this function.

2. *Secretion.*—It has been noted by Ivy and his co-workers that in a dog with a gallbladder fistula and cystic duct obstruction, about 20 cc. of a mucoid fluid is secreted in twenty-four hours. The ducts secrete a slight viscous substance. In common duct obstruction, green fluid is noted with a relatively normal gallbladder, and "white bile" is a result of concomitant gallbladder disease or absence of the organ, and is associated usually with a hepatitis.

3. *Motor Activity.*—Ivy has shown that a hormone found

in the duodenum, which he has designated as cholecystokinin, is the chief stimulus to gallbladder contraction. Acids and fats are excitants to this hormone. Of such practical excitants, egg yolk and cream are the most effective. Atropine relaxes and morphine increases gallbladder tone, while pituitary solution causes some expulsion of bile, but these do not abolish the action of cholecystokinin.

The contraction of the gallbladder depends on three factors: the tone of the duodenum, the tone of the sphincter of Oddi, and the resistance of the flow of bile from the common duct into the duodenum. The functions of the sphincter of Oddi relate to the filling and emptying of the gallbladder as well as to the prevention both of the regurgitation of bile and the transmission of pressure from the duodenum to the common bile duct. Thus when the sphincter contracts, the gallbladder relaxes and fills and when the sphincter relaxes, the gallbladder contracts and expels its contents. This relationship is further seen in the sphincter becoming incompetent when the gallbladder is removed, but later its competency is recovered and the ducts dilate.

Any increase in duodenal tone may delay as well as any decrease in tone may increase the gallbladder evacuation. Atropine decreases and morphine increases such duodenal tone. The sphincter of Oddi can resist up to 75 cm. of bile pressure, whereas the maximum expulsion of the gallbladder is 30 cm. of bile pressure. Therefore, a spastic sphincter can resist gallbladder evacuation.

Three pathologic-physiologic processes may follow from a disturbed sphincter of Oddi-gallbladder relationship:

1. Increased activity both of the gallbladder and the ampulla with rapid emptying. This is known as the hyperkinetic type of evacuation.

2. Contraction of the gallbladder against spasm of the sphincter resulting in biliary colic and called "hypertonic dyskinesia."

3. An atonic gallbladder in consequence of a spastic sphincter with a resulting heavy, aching sensation.

Let us now revert to several of the questions asked at the outset. How much does the gallbladder contribute to the

complaints? How shall the diagnosis be established? Who shall be treated medically and who surgically?

**The Differential Diagnosis.**—If one suffers with frequent attacks of colic caused by calculi, the removal is indicated and the results are striking. On the other hand, little relief can be expected of surgery from mild symptoms—often due to other conditions—and mild gallbladder changes. Here there can be no real consolation that the excised gallbladder showed some alteration. Not only is there no agreement among pathologists as to what is a normal gallbladder, but rarely is a gallbladder pronounced normal on the basis of microscopy.

The problem becomes relatively easy when the following are obtained: (1) a satisfactory account or evidence of one or more attacks of biliary colic, with or without fever, chills and jaundice; (2) residual tenderness following such painful episodes; (3) possibly indigestion between attacks, characterized by flatulence, bloating and discomfort. However, if diagnosis is to be improved, if a better selection of cases for medical and for surgical therapy is to be made, the possible presence of any one of several other conditions, or a combination of them resulting in similar, if not in identical complaints,

Marked . . . .	147	113	93 82.2%	20 17.8%
Total . . . . .	610	447	332	115

Note. Degrees of pathologic change "with stone" and "without stone" not shown because symptomatic results were not statistically significant.

\* From Wilson, W. D., Lehman, E. P., and Goodwin, W. H.: Jour. Amer. Med. Assoc., 106: 2209-2213 (June 27), 1936.

must be more readily recognized. Thus, gallbladder colic may be mimicked by tabes dorsalis, perforating peptic ulcer, renal calculi, hydronephrosis, root pains of spinal and vertebral lesions. It will be important to know whether the colic is due to stone or to the already referred to pathologic-physiologic state of the contraction of the gallbladder against a spastic sphincter of Oddi, designated as hypertonic dyskinesia.

The jaundice suspected of being obstructive may be intra-hepatic, or hemolytic, or may be manifestations of familial or congenital hyperbilirubinemia, pernicious anemia or carotinemia.

How are these conditions to be differentiated? In many instances, the mere thinking of these possibilities plus adequate history taking—the most important single method of diagnosis—will go a long way toward clarification. In addition to a satisfactory physical examination, it will be necessary to resort to simple laboratory procedures, many of which the progressive practitioner will be able to do for himself.

Satisfactory evidence of lues and the nature and extent of therapy, Wassermann reactions on blood and spinal fluid, should solve the question of tabes. Plain plates of the abdomen will reveal radiable biliary, renal, ureteral or urinary-vesicle calculi, vertebral lesions, as well as subdiaphragmatic gas as seen in perforated peptic ulcer. Intravenous urography, now a relatively simple procedure, the application of which is not contraindicated in jaundice, will furnish additional data of a positive or negative nature, either of which are obviously important in differential diagnosis. The rare instance of jaundice of pernicious anemia will be recognized by an adequate blood study which should be part of the routine of a complete examination. Carotinemia may be suggested by the history. It can be eliminated readily as follows:

Add an equal part of chemically pure acetone to the serum to be used in determining the icteric index. The mixture, then, is centrifuged, and carotin as well as hemolyzed red blood corpuscles and proteins are precipitated. The intensity of the supernatant fluid of clear, yellow serum is tested against known icteric index standards. The result is multiplied by two because of acetone dilution. This sum represents the extent of serum bilirubinemia and establishes the true icteric index.

Hemolytic jaundice, particularly the typical type, is readily recognizable. Unlike obstructive jaundice, it is chronic, of long duration, is relatively mild, presents a variable but persistent slight jaundice, and manifests splenomegaly. The essential laboratory data reveal fragility changes and spherical microcytes in the peripheral blood, the latter being regarded by William P. Thompson as pathognomonic of the disease. The van den Bergh reaction is indirect. Since many with hemolytic jaundice eventually develop biliary calculi, both hemolytic and obstructive jaundice may be present simultaneously.

The common and more difficult differential diagnostic problem is that of intrahepatic from extrahepatic jaundice. The former is not always painless and the latter is not always strikingly painful. The distinction is important since intrahepatic jaundice is a medical problem and extrahepatic jaundice may necessitate surgery. The solution can be aided greatly by the proper application of the galactose tolerance test shortly after the onset of jaundice. This method is based on the facts that galactose is practically unutilizable by any structure other than the liver, that there is no renal threshold for the excretion of this carbohydrate, and, unlike glucose, galactose is unmodified by the activity of the endocrine glands. Thus, in the sudden hepatic involvement of intrahepatic jaundice, before there is time for ample hepatic regeneration, excessive galactose is excreted in the urine. Following an overnight fast without any other food, galactose totaling 3 Gm. or more in urine collected at five consecutive hourly intervals subsequent to the ingestion of 40 Gm. of galactose, is indicative of hepatic damage as being the cause of jaundice. The negative finding will not be significant unless the test is done early in the course of the disease, since a day or two may be sufficient, in some cases, to allow the liver to compensate. The technic is very simple; any practitioner equipped to do Benedict's or Fehling's qualitative and quantitative reactions will be able to perform this test. Those interested are referred for further details, which space does not permit to present here, to the articles of Shay and his co-workers, to whom great credit is due for reviving, modifying and stimulating interest in this important differential diagnostic method.

The teaching has been that relatively long-standing bloat-

ing, fulness, flatulence, indefinite dyspepsia or poorly localized attacks of abdominal pain, with or without nausea and emesis, particularly if they occur in women who have been pregnant and especially if they are overweight, are likely to be due to gallbladder disease. Since the advent of cholecystography, the diagnosis appeared more certain to some, if the x-ray were in any wise suggestive of disease. This teaching seems to be in need of revision. It is not believed that many with only such symptomatology can be said to have it as a result of gallbladder affection, even if there be evidence of some pathology in that organ. It must be remembered that coincidental occurrences—pathology and symptoms—do not always indicate a cause and effect relationship. Besides, the more recent evidence from first-rate surgical clinics points out that removal of the assumed cause—the gallbladder—does not bring anticipated relief in this type of case sufficiently often.

If not the gallbladder, what, then, may account for such difficulties? Atypical manifestations of peptic ulcer, small intestinal deviations, and renal lesions reflexly, often give rise to similar complaints. The same symptoms—sometimes designated as gallbladder dyspepsia—will also be found in some with low basal metabolic rates, in chronic nervous exhaustion with or without demonstrable changes in tone and/or secretion of the digestive apparatus, in constitutional inadequacies with and without affective disorders in the irritable colon, and in some with any change in digestive function on a psychogenic or neurogenic basis.

First thinking of, and then directing the history into the channels of such possibilities, will go far toward untying the knot. Thus, queries indicating unusual sensitiveness to cold, usually but not always with easy fatigue, should suggest the possibility of a low basal metabolic rate. And answers to such simple questions as, "Do you think the world is treating you right?" "Are you sad?" "Do you sleep well?" will often be found to be the first steps toward revealing temperament, depression, attitude, hopes, anxieties and destroyed ambitions, maladjustments and other psychogenic factors at play. To pay attention to this phase only after organic disease has been eliminated is an error, for often psychogenic and organic disturbances are concomitantly present, and complaints actually

flowing from the former are erroneously attributed to the symptomless structural changes. The rôle of pathologic physiology, not due to structural defect, in the production of symptoms, has been too long neglected under the influence of the German school of pathologic anatomy and the rapid progress of laboratory medicine.

It has been pointed out that the greatest benefits from surgery are restricted to those who have had biliary colic due to stone and in whom the gallbladder involvement is not mild. How is one to ascertain the extent of pathology and the presence of stones? Two valuable laboratory adjuncts are available: the nonsurgical biliary drainage of Lyon, and cholecystography. *x*-Rays may be corroboratory but will not add much information to those experienced with the former. Bockus, Shay, Willard and Pessel have demonstrated that cholesterol crystals and calcium bilirubinate in duodenal aspirates ("B" bile) are pathognomonic and cholesterol crystals highly suggestive of stone, while many white blood corpuscles indicate infection. Cholecystography is more widely used and

TABLE 4  
CHOLECYSTOGRAM AND PATHOLOGIC CHANGE\*

Degree of pathologic change.	Normal shadow.	Good shadow.	Poor shadow.	No shadow.	
With stone:					
Mild.. . . .	3	4	0	1	
Moderate	2	7	25	76	
Marked	0	0	10	30	
Total	5	11	35	107	158
With and without stone:					
Mild	14	16	17	12	
Moderate	6	12	38	93	
Marked	0	0	12	32	
Total	20	28	67	137	252

Note: The part of the table concerning "without stone" has been eliminated because the results were not statistically significant.

\* From Wilson, W. D., Lehman, E. P., and Goodwin, W. H.: Jour. Amer. Med. Assoc. 105: 2209-2213 (June 27), 1936.

is very helpful. Its careful application gives results upon which anatomic-pathologic change in the gallbladder as well as functional alterations may be detected. In studying the accuracy of cholecystography in determining cholelithiasis, Case found stones in 95.7 per cent of cases where the report was either "no shadow" or "stone positive." Cholecystography, when considered with a good history, has been found accurate in 90 to 95 per cent of cases by Palmer and Ferguson. On the other hand, where the gallbladder was removed in the face of normal or good cholecystographic shadows, 50 per cent of the results were said to be poor. It is conceivable that some of the 50 per cent of good results may be due to psychotherapy brought about by surgery; this will be referred to shortly.

**Therapy.**—*Prophylaxis.*—Little is known concerning this. Ivy suggests the adequate daily intake of fat to evacuate the gallbladder as a phase of antepartum care and in the atonic symptomless gallbladder.

*Cases selected for surgery* should be limited to those who present stones, relatively advanced gallbladder changes and in whom there is evidence of *more than one attack of biliary colic*. To establish the last is important for two reasons: (1) Blackford, King and Sherwood in following 100 cases of biliary colic found no recurrences of colic in 40 per cent of patients after the initial examination. (2) Maynard reports that in 223 cholecystectomies, 24 gallbladders were found to be normal. Seventy per cent of the latter's possessors regarded their operations as successful, a psychotherapeutic effect achievable by less drastic means.

*Cases Selected for Medical Management.*—These should consist of all of those who fail to meet the criteria for surgical intervention.

*Dietotherapy.*—In acute gallbladder disease, fat and fruit juices are interdicted. The former may result in the contraction of an organ requiring rest, and the latter may unduly chemically stimulate a concomitantly disturbed digestive tract. In the chronic disorders, individual tolerance to these foods must be ascertained. In general, a well-balanced dietary in which the physical, chemical and mechanical factors are reduced (smooth diet) will suffice.

*Pharmacotherapy.*—It is believed that the dyspeptic manifestations ascribed to gallbladder disease, are—in many instances—due to an irritable digestive apparatus. Magnesium sulfate, intended to relax the sphincter of Oddi and to stimulate bile flow, and the various bile salt preparations, most of which contain either calomel, cascara or phenolphthalein, eventually become intestinal irritants and exaggerate both the dysfunction and symptoms. Atropine and its derivatives, sedation, and oil by mouth and by rectum are helpful.

*Psychotherapy.*—Finally, the patient is to be assured that the extent of the disease bears little or no relation to his complaints, and that the prognosis is good. Further, he is to be shown how his temperament as the soil, and his responses to his problems and environment as the seeds, bring forth the flower of pathological physiology accountable for his complaints. Adjustment of the intelligent patient to whatever complaints arise or continue on this basis will often follow.

*Involvements Following Surgery for Cholecystic Disease.*—Following surgery, the recurrence of three symptoms should excite immediate attention. These are pain, jaundice and possibly dyspepsia. There are three causes for this: (1) an hepatitis which may arise from the gallbladder infection, carried by the lymphatics, or from an ascending cholangitis. This can be determined early by a serum bilirubinemia, a direct van den Bergh reaction, and the retention of bromsulfalein weeks to months after surgery. Here it is hoped that the condition will subside spontaneously. (2) A stricture or stone in the common duct presents, in addition to jaundice and colic, chills and fever and is in need of surgical intervention to prevent an ascending cholangitis with biliary cirrhosis, splenic enlargement and finally hepatic insufficiency. (3) The more common postcholecystectomy distress is seen not infrequently shortly after operations, and sometimes later. The early episodes may be associated with the passing of mucus and debris, or with slowly regressing inflammation; the later attacks may be concerned with dilatation of the ducts and spasm of sphincter of Oddi. Here the medical management is not unlike that already suggested for nonsurgical gallbladder disease and simulating disturbances.

## CLINIC OF DR. THOMAS P. SPRUNT

BALTIMORE

---

### FACTORS OF INTEREST IN THE DIAGNOSIS OF LIVER DISEASE

THE liver is the largest of the glandular structures; it is the center of many metabolic activities and in its relation to the portal circulation it occupies a strategic position between the gastro-intestinal tract and the rest of the body. One might expect it to be vulnerable. Although there are indications of minor disturbances of the liver in many generalized diseased states, particularly in those associated with fever and with anoxemia, major diseases of the liver are comparatively rare. This relative rarity would be surprising were we not so imbued with the idea of this organ's unusual reserve power and its remarkable regenerative capacity.

It has been pointed out many times that the most obvious clinical manifestations of liver disease have to do with the excretion of bile, with its relation to the portal circulation and with its variability in size. Our chief reliance in hepatic diagnosis must rest upon careful history taking and the usual bedside methods of observation and physical examination with particular emphasis upon the three fundamental factors just mentioned or the corresponding pathologic phenomena of jaundice, portal obstruction and enlargement or shrinkage of the liver. This method of approach often suffices but in the difficulties of differential diagnosis that may arise reliable tests of the functional capacity of the liver become highly desirable. It is obvious that with an organ of such multiplicity of function, no single all-embracing test need be expected. Many methods have been devised to test each of the known functions

of the liver and a few of them seem to many observers to be helpful under certain conditions. No attempt will be made to list these tests but after a consideration of the fundamental clinical factors we may consider briefly some of the tests that have come to be a part of the clinical armamentarium in many hospitals.

**Jaundice.**—Probably the most important clinical sign of liver disease is jaundice and the study of its pathogenesis has been most stimulating and instructive. Bilirubin derived from hemoglobin is brought in the circulation to the liver cells which excrete it along with other constituents of the bile into the bile canaliculi whence it passes down the bile passages into the intestines. Here the bilirubin is reduced to urobilin, a part of which is absorbed, carried back to the liver and again excreted into the bile. When the excretory function of the liver is depressed, the urobilin may accumulate to some extent in the blood stream and be excreted by the kidneys into the urine. Urobilinuria is hence regarded as an indication of depressed activity on the part of the liver.

A useful concept emphasized by Rich<sup>1</sup> is the division of jaundice into two main types, retention jaundice and regurgitation jaundice.

In retention jaundice, the bilirubin circulating in the blood stream may not all be excreted by the liver cells and accumulates in the blood. Under these circumstances the bilirubin seems to be bound in some way, perhaps to the plasma proteins, gives an indirect van den Bergh reaction and does not pass through the kidneys into the urine (acholuric jaundice). A retention jaundice, associated with milder forms of liver injury, cloudy swelling or atrophy of cells, is due to an increased formation of bilirubin together with a depressed excretory function of the liver due in turn to different factors, particularly anoxemia, fever, and in the case of the newborn to immaturity of the liver cells. This milder type of jaundice and of liver injury is associated with such diseases as the hemolytic anemias, congestive heart failure, malaria and lobar pneumonia.

In regurgitation jaundice, on the other hand, the bilirubin is excreted by the liver cells and then escapes from the bile canaliculi into the tissue spaces and blood sinusoids of the

liver, either by reason of obstruction of the larger bile ducts or by necrosis of the liver cells. In this case, not only bilirubin but the whole bile gets into the blood stream. The bile pigment now is not bound, it gives a direct van den Bergh reaction and is readily excreted by the kidneys into the urine (choloric jaundice). This is the type of jaundice associated with the major liver disorders. The careful observation of the occurrence of bile pigments in the tissues, in the urine and in the intestinal tract, and laboratory studies of the qualitative and quantitative relationships of bilirubin in the blood are the most valuable diagnostic features in acute liver disease and may be useful also in chronic conditions.

**Portal Obstruction and Other Causes of Water Retention.**—Until recently it has been generally assumed that ascites in liver disease was due entirely to obstruction of the portal radicles within the liver and that the dependent edema sometimes noted was caused by the pressure of the ascitic fluid upon the vena cava. It is now realized that this does not account for all the water retention in liver disease.

The presence of ascites of even moderate degree is usually an obvious clinical finding. The swollen abdomen is in striking contrast to the pinched and emaciated appearance of the body elsewhere. In addition to the ascites or even in its absence one may find other evidence of portal obstruction in the development of collateral venous channels. Dilated veins may be readily visible on the thoracic and abdominal walls, dilatation of hemorrhoidal veins may be noted and by the use of a thick barium paste esophageal varices may be readily demonstrated by roentgenography. The presence of blood in the vomitus or in the stools may signal the presence of esophageal varices.

The occurrence of water retention in both acute and chronic liver disease in the absence of ascites has been noted by a number of observers. Jones<sup>2</sup> has emphasized the occurrence of a spontaneous diuresis at a certain stage in acute liver disease and inasmuch as this is followed usually by rapid clinical improvement he presents it as a valuable and favorable prognostic indication.

One probable cause of the disturbance in the fluid balance in liver disorders may be related to the blood plasma proteins.

Several observers<sup>3</sup> have noted some disturbance of the plasma proteins in all types of liver disease. This change is especially notable in chronic diffuse diseases of the liver (cirrhosis) where the total plasma proteins are reduced and particularly the albumin fraction. The globulin fraction may be less reduced or it may actually be increased with the result of an inversion of the albumin-globulin ratio. In the reports of several studies of this type the albumin of the blood plasma has been usually below 2.5 Gm. per 100 cc. in cases of cirrhosis. Several students of this problem believe that the hypo-albuminemia may itself be an indication of hepatic insufficiency. Myers and Keefer<sup>4</sup> were unable to increase the plasma proteins by high protein diet in their patients, hence the finding of low blood protein values does not seem to indicate the advisability of a high protein diet in therapy.

Changes in the size, shape and consistency of the liver are of value primarily in calling attention to a pathologic change in the organ and may also be of differential diagnostic significance. Very familiar to all of us is the uniformly enlarged and tender liver of chronic passive congestion. I may cite further the slightly to moderately enlarged and slightly tender liver in its acute diffuse disorders, the firm, easily palpable liver edge in cirrhosis, and the large, hard, and perhaps, irregular liver in neoplastic states. Observations of changes in size and in contour may be of great value in following individual cases. The originally enlarged liver in an acute diffuse disease may become gradually or rapidly smaller and its disappearance beneath the costal margin may accompany other distressing features of an acute yellow atrophy.

**Functional Tests of Hepatic Insufficiency.**<sup>5</sup>—In the search for aid in the study of liver diseases and in problems of differential diagnosis tests have been devised for the study of many of its functions including those having to do with the metabolism of carbohydrates, of proteins, and of fats, its detoxication power and its ability to excrete certain substances into the bile. Some of these tests have come into fairly general use and this may be taken perhaps, to some extent, as a measure of their helpfulness. In view of the great reserve power in all these functions the tests are of possible importance only when lesions are widespread or diffuse throughout the liver.

They are usually negative, for example, in such conditions as solitary abscess or sparsely scattered metastases in the organ.

In cases with jaundice the study of the bile pigments in the urine, in the stools, in the duodenal contents, and in the blood serum is distinctly helpful. The indirect and the direct reactions of the van den Bergh test for bilirubin in the blood serum distinguish between retention and regurgitation jaundice. The presence of a direct van den Bergh reaction may reveal the presence of a subclinical jaundice. By means of the quantitative van den Bergh or the simpler icterus index the amount of the bilirubin in the blood serum may be determined from time to time and its increase or decrease may be of considerable value in the observation of a puzzling case. In diffuse necrosis of the liver there is usually a steady increase in the serum bilirubin to a maximum and then with regeneration of cells a gradual fall in bilirubin values. In obstructive jaundice, on the other hand, there is a rise to a moderate level and then a sustained plateau with comparatively minor fluctuations in the values of serum bilirubin.

In cases without jaundice the study of the behavior of injected bilirubin indicates that this may prove to be a more delicate test than most others that have been devised. It will be noted that the substance used is one normally and constantly being excreted by the liver and its use as an excretory test is therefore quite rational. So far the expense of the pure bilirubin and the somewhat involved technic have militated against its general usefulness.

Other excretory tests are based upon the fact that several dyes (phenoltetrachlorophthalein, bromsulfalein, rose bengal) have been found that are excreted entirely or almost entirely into the bile. They are also recognized quantitatively when retained in the blood serum and are measured by colorimetric methods. These tests have become popular and are of particular value in the absence of jaundice or when the degree of jaundice is minimal. Obviously when there is marked jaundice the retention of the dye in the serum may merely parallel the degree of the jaundice. Sometimes there is found a marked disproportion of dye retention in cases of small degrees of jaundice. Probably the most widely used of these tests is the bromsulfalein test. In the performance of the test 5 mg.

of the dye per kilogram of body weight is injected intravenously; at the end of one-half hour a specimen of blood is obtained and examined. The retention of a measurable quantity of the dye, 10 per cent or more, is considered definitely abnormal and indicative of liver damage.

One of the carbohydrate tests of liver function, namely the galactose tolerance test, is sometimes of considerable value and particularly in markedly jaundiced patients in the differentiation between diffuse liver necrosis and duct obstruction. The test is of value especially in the early stages of the illness when the liver cell destruction on the one hand is at a maximum and when on the other hand the damaging effect of duct obstruction on the liver cells is still slight. When performed within two weeks of the beginning of the jaundice the test has considerable differential value. In the performance of the test, after a twelve-hour fast the patient is given 40 Gm. of galactose in 250 to 500 cc. of water; no food is permitted during the test but water can be taken as desired; the urine is collected for five hours and examined for sugar; the excretion of more than 3 Gm. of galactose is considered abnormal.

Other carbohydrate tests are occasionally used, namely, the levulose tolerance test and modifications of the glucose tolerance test, but they usually parallel more or less the findings with bromsulfalein and in general seem less helpful than the excretory tests.

Methods based upon the protein metabolism of the liver have not been strikingly helpful and are not widely used. If the changes in the blood plasma proteins may be considered in this light they may be of value in the absence of other causes of hypo-albuminemia.

The study of fat metabolism in this relationship is relatively new and not yet well evaluated. I am constrained to mention one such test because of its intriguing possibilities. Jones and Fish<sup>6</sup> have studied the curve of the plasma fatty acids after the injection of 0.5 cc. of adrenalin. They describe a normal curve and three different types of abnormal curves in association with diseases of the liver. They feel that the test offers prognostic aid in patients with liver disease and apparently regardless of the type of hepatic involvement. The curves A and B indicate a relatively excellent prognosis even

in the face of apparently severe liver injury provided adequate treatment is instituted, while the curves C and D suggest a prognosis of chronic invalidism or of a relatively short survival period. As far as I know these findings have not been extended or confirmed.

**Acute Diffuse Disorders of the Liver.**—The so-called "simple" or "catarrhal jaundice" may be taken as an example of an apparently primary acute liver disorder. It is now generally agreed that these cases represent a necrosis of liver cells rather than obstruction of the bile ducts. There are many grades of severity. A prodromal period of several days presents the symptoms of anorexia, gaseous eructations, feelings of fullness and of pressure in the epigastrium, nausea, and other gastro-intestinal symptoms. There may be slight fever for two or three days. The jaundice is obvious after a few days. If observed very early the van den Bergh test in the blood serum may give an indirect reaction but it soon changes to the direct reaction and bilirubin and bile salts are found in the urine. The stools may become progressively lighter in color and sometimes are completely acholic. As a rule the jaundice increases to a maximum and then gradually recedes. The liver is somewhat enlarged and often tender. The spleen is palpable.

In the presence of such a picture of a painless jaundice in a patient in the first half of life one is rarely in doubt concerning the diagnosis. Quite the opposite however is true of patients of middle age or more advanced age for these symptoms and signs may be duplicated by a gradual closure of the common bile duct by pressure from without, as from a carcinoma in the head of the pancreas. Here if used early the galactose tolerance test may be helpful. It may be necessary to observe the patient carefully for several weeks with close observation of the urine, of the stools and occasional quantitative tests of bilirubin in the blood serum. If the blood bilirubin reaches a maximum and then recedes and continues downward a favorable signal has been given. Jones and Eaton<sup>2</sup> suggest that a chart be kept of the daily fluid intake and urinary output so that one may recognize, when it occurs, the period of spontaneous diuresis that also signals the onset of recovery. In the most difficult cases, when the serum bilirubin has been indeterminate in its course for several weeks and the patient re-

mains deeply jaundiced, a surgical exploration is definitely indicated.

Although the prognosis in most cases of acute liver disorder is favorable, the course in certain instances is progressively from bad to worse, ending with the typical features of acute yellow atrophy with shrunken liver, deep jaundice, persistent vomiting, bleeding into the skin and mucous membranes, apathy, headache, confusion, delirium and unconsciousness.

The great diversity of etiologic agents in acute liver disorders may be appreciated by a study of the table from Bockus and Tumen,<sup>7</sup> entitled:

### HEPATOCELLULAR JAUNDICE\*

#### (A) CHEMICAL POISONS

1. Arsenobenzol derivatives—arsphenamine, neoarsphenamine, tryparsamide, etc.
2. Quinoline derivatives—cinchophen, atophan, quinophen, phenoquin, acophanyl, hydrocin, oxyliodide, arcanol, etc.
3. Halogen group—chloroform, carbon tetrachloride, tetrachlorethane, ethyl chloride, ethyl bromide, trichlorethylene, tribromethyl alcohol (avertin).
4. Aromatic organic compounds—trinitrotoluene (TNT), dinitrobenzene, dinitrophenol, picric acid, toluylenediamine, and acriflavine.
5. Miscellaneous—arseniuretted hydrogen, phosphorus, alcohol, lead, mercury, synthaline, snake venom.

#### (B) VEGETABLE POISONS

Mushroom poisoning.

#### (C) BACTERIAL OR VIRUS POISONS

Epidemic catarrhal jaundice (infectious jaundice), pneumonia, yellow fever, influenza, food poisoning, typhoid, paratyphoid, typhus and parenteric fevers, streptococcus septicemia.

#### (D) PROTOZOAL POISONS

Syphilis—icterus syphiliticus praecox, specific chronic interstitial hepatitis. Spirochaetosis icterohaemorrhagica, amebic dysentery, malaria, kala-azar, relapsing fever.

#### (E) MISCELLANEOUS

Idiopathic nonepidemic catarrhal jaundice (some types), toxemias of pregnancy, uremia, goiter, acidosis of recurrent vomiting in children, portal cirrhosis.

Certainly such a formidable list of potential poisons emphasizes the care with which the history must be taken.

\* Bockus, H. L., and Tumen, H. J.: *The Cyclopaedia of Medicine*, editor, G. M. Piersol, vol. vii, p. 588, F. A. Davis Co., Publishers.

In addition to these exciting causes of the disturbance the physician will be interested also in the known predisposing causes of acute liver disease, namely, a depletion in the glycogen reserve of the liver, anoxemia, the presence of a preexistent chronic diffuse disease of the liver, pregnancy and the puerperium, toxic thyroid states, or the presence of a syphilitic infection.

By the term **chronic diffuse hepatic disease** we mean **cirrhosis** since the latter term has come to mean a more or less diffuse increase in the fibrous tissue within an organ. The differentiation into portal cirrhosis and biliary cirrhosis is useful clinically and may have an important bearing from the therapeutic standpoint. The first type indicates an involvement particularly of the portal system, while the term biliary cirrhosis indicates a disease associated especially with chronic jaundice. In the later stages of each, both jaundice and portal obstruction may be present but the historical review of the case usually makes the distinction clear. The biliary type affects patients of the younger age group, while as a rule the portal type begins after forty. Both may have the history of an insidious onset but there is rather more likelihood of some evidence in the previous history of biliary or of hepatic disease in the biliary type than in the portal. The spleen is usually palpable in both types. The liver is uniformly enlarged in biliary cirrhosis and variable in size in portal cirrhosis. The size of the cirrhotic liver is determined not only by the disappearance of parenchymatous cells and the contraction of fibrous tissue that tend to decrease the size of the liver but also by the storage of fat and perhaps other materials that tend to make the organ larger.

In the well-developed portal cirrhosis the picture is unmistakable—the abdomen swollen with ascites, palpable spleen, dilated veins, and the pinched, emaciated subicteric facies. Advanced cirrhosis is the favorite proving ground for functional tests. Perhaps the most valuable here is the bromsulfalein excretion test and it should prove helpful if for any reason there may be a doubt as to the cause of the ascites. The blood plasma proteins are reduced and the hypo-albuminemia is especially striking. The laboratory examination of the ascitic fluid should be of value in differentiating between a transudate and an exu-

date. A complete study may be necessary for a full evaluation of the situation in cases where a chronic peritonitis or a tuberculous peritonitis has developed in the course of a cirrhosis, a not unusual combination.

Banti's disease, or primary splenomegaly, with the ultimate development of cirrhosis and portal obstruction is an important subdivision of the portal cirrhotoses for the surgical removal of the spleen may be an efficacious therapeutic procedure particularly if the operation is not too long delayed. The diagnosis may be made by the history of primary splenic enlargement or by the disproportionately large size of the spleen, together with the marked secondary anemia.

In biliary cirrhosis evidence of biliary obstruction or of infection of the biliary passages by examination of the duodenal contents suggests again definite surgical implications.

The occasional finding of a well-marked cirrhotic liver at necropsy in patients dead from some other cause and in whom the presence of cirrhosis was not suspected during life encourages us to believe that more careful clinical study and the judicious use of functional tests may enable us to make a diagnosis of liver cirrhosis earlier at a stage when therapeutic endeavors may be more successful than they are at present. The patient of middle age with a definite history of chronic and excessive alcoholism and of gastro-intestinal disturbances should certainly be fully investigated from the standpoint of a possible cirrhosis of the liver. Minimal requirements for such a study should include a careful physical examination, a roentgenographic study of the esophagus, the van den Bergh reaction of the blood serum, the estimation of the blood plasma proteins, and the bromsulfalein excretion test.

## CLINIC OF DR. E. COWLES ANDRUS

FROM THE DEPARTMENT OF MEDICINE AND MEDICAL CLINIC,  
THE JOHNS HOPKINS UNIVERSITY AND HOSPITAL

---

### THE SIGNIFICANCE OF ACUTE HYPOTENSION; ITS ETIOLOGY AND TREATMENT

IN a variety of conditions the systolic arterial blood pressure, as customarily measured, may be observed to be below the accepted normal standards, which vary with age from 100 to 140 mm. of mercury. But the term "hypotension" had best be reserved to designate a systolic pressure persistently less than 100 or—and more important—a pressure abruptly reduced from a value within normal limits or even above. The chief symptoms of this condition such as dizziness, "faintness," weakness and fatigue, appear to depend more upon insufficient blood flow than upon the precise level of arterial pressure. Certain others—hyperpnea and tachycardia—are suggestively analogous to the effects produced experimentally in animals by the sudden reduction of blood pressure within the carotid sinus.

The subject has been fully reviewed in the excellent monograph by Friedlander.<sup>3</sup> In this paper the mechanisms concerned with acute hypotension will be briefly discussed and illustrated.

*The control of arterial blood pressure* is normally effected by the coordinate interplay of three major factors: (1) the cardiac output, (2) the volume of the circulating blood, and (3) the state of the blood vessels, including the peripheral vascular resistance. These are interdependent, as a consequence of certain reflex mechanisms mediated through sympathetic and parasympathetic pathways, to such a degree that variations in one factor lead to compensatory changes in the others. Certain qualifications of these factors merit emphasis.

**Cardiac Output.**—Provided the venous inflow remains constant the output per minute of the normal heart remains unchanged despite considerable alterations of arterial resistance or of cardiac rate. On the other hand, increase or decrease in the volume of blood entering the heart from the great veins results in conspicuous increase or decrease in cardiac output. It is thus apparent that the output of the heart is dependent principally upon the condition of the venous circulation, and that the contribution of cardiac output to arterial pressure depends upon the relation between the amount of blood leaving the arteries via the capillaries and that entering the ventricles from the auricles and veins. The optimum conditions are fulfilled when venous inflow is sufficient to fill the ventricles during diastole to their maximum capacity for discharge. If ventricular filling is impeded, as in some cases of mitral stenosis or with constrictive pericarditis or pericardial effusion, the systolic pressure diminishes unless balance is restored by arteriolar constriction. Obviously, too, though venous inflow be unaltered, cardiac output will fail if the functional capacity of the heart muscle is reduced (myocardial disease, coronary occlusion) or if the rate of the heart beat is so excessively rapid as to prevent adequate filling during diastole (paroxysmal tachycardia, auricular flutter, or auricular fibrillation with rapid, irregular ventricular beat).

**Volume of the Circulating Blood.**—Reduction of total blood volume (*e. g.*, following hemorrhage or severe diarrhea) may occur without demonstrable fall of arterial blood pressure in so far as this may be met by reduction of the capacity of the vascular system by constriction of the vessels. Beyond this point pressure in the arteries may fall due to insufficient filling. But, with or without alteration of the *total* volume of circulating blood, changes in the *distribution* of the blood may strikingly influence the arterial blood pressure. The most effective element of blood volume as regards arterial pressure is that portion thereof contained at any moment in that section of the cardiovascular system between the heart and the arteriolar ends of the capillaries. Any shift of blood volume to the disadvantage of this portion will lead to a reduction of arterial pressure unless compensation can be effected by con-

striction of arteries, arterioles and the arteriolar-capillary limits.

**State of the Blood Vessels Including Peripheral Vascular Resistance.**—There is little proof that changes in elasticity of the larger arteries such as develop with advancing age contribute to hypotension, although the effect of hypotension in provoking symptoms of inadequate blood flow to the brain is undoubtedly enhanced if such flow is already impaired by sclerotic changes in the cerebral arteries. There is evidence that loss of intrinsic venous tone with consequent "pooling" of blood in splanchnic or dependent areas, may, under certain conditions, contribute to the development of circulatory collapse, and that the massaging support rendered to the veins by the movements and tone of the muscles of the extremities is of considerable importance in forwarding the return of blood from the periphery. But in the vascular field between arteries and veins lie the chief resources for the sensitive control of arterial pressure. Upon the integrity of these mechanisms depends the adaptation of blood flow to meet local circulatory requirements, and to counterbalance the hydrostatic effects of changes in posture.

The peripheral vascular resistance is determined by the total cross-sectional area of the smaller vessels—arterioles, capillaries and probably the venules. The caliber of these is regulated in part directly and in part by vasomotor nerves. They react diffusely or locally to changes in the temperature of their contents or environment—dilating with heat and constricting with cold—and to chemical alterations in the blood or tissue fluids—dilating under the influence of certain blood-borne drugs or substances produced elsewhere in the body (histamine) and constricting under the action of others (adrenalin). The products of tissue metabolism or injury have a decided dilating effect upon this portion of the vascular field. Finally, by far the most sensitive control of vascular caliber is reflexly mediated by the vasomotor nerves—chiefly vasoconstrictor—from centers in the medulla and spinal cord.

The accepted standards for blood pressure have already undergone some revision since this observation became a routine with the introduction of manometric methods. Thus, clinical experience, as well as that of insurance companies, has

emphasized the significance of the diastolic values as well as the systolic, particularly in cases of hypertension. Here too, the importance of repeated estimations of blood pressure has become apparent in view of its fluctuation in some individuals at rest between normal and high values. Persistent hypotension has not escaped detection in the routine measurements of blood pressure, but, except as a result of special studies,<sup>6</sup> too little information is available concerning the transient changes in blood pressure which result from alterations of posture.

When a human being rises from the horizontal to the vertical position and stands quietly, the physiologic demands upon the circulation are considerably altered. Probably least significant is a slight but definite increase in the total oxygen consumption (5 to 20 per cent). More important is the hydrostatic effect of gravity upon the blood in the vessels. This tends to enhance the flow of blood downward out of the arteries into the veins below the heart but to hinder the flow upward in the dependent portions of the venous system.\* All of the above-mentioned factors fundamental to the control of the arterial blood pressure are thus adversely affected: a larger proportion of the total blood volume tends to accumulate on the venous side of the circulation and, despite this, the return of venous blood to the heart, so essential to adequate diastolic filling of the ventricle, is decreased, and systolic discharge is thus diminished. Moreover, the circulation to the medullary and cerebral centers suffers the potential disadvantage of a change from approximately heart level to a position 25 cm. or more above.

In the normal individual compensatory circulatory adjustments are quickly made to meet these conditions and are more or less adequately maintained. The systolic blood pressure alters only slightly. The diastolic pressure rises, reducing the pulse pressure and indicating constriction of the peripheral arterioles in accommodation to the tendency toward increased outflow. The cardiac rate increases, maintaining the total cardiac output by increasing the number of ventricular systoles and thus accommodating to the decreased diastolic filling con-

\* Of the total capacity of all the blood vessels two thirds or more lie below the level of the heart in the erect posture.

sequent upon the decreased inflow of venous blood. The integrative control of these mechanisms is still not clearly understood, but the importance of the various vascular and nervous phenomena is emphasized by the results observed when one or another phase thereof is temporarily or permanently impaired.

**Imperfect Circulatory Adjustment to Changes in Posture.**—Probably everyone has experienced a transient sensation of weakness and dizziness upon standing erect after sitting or lying in a hot bath. The vascular dilatation produced by heat is often widespread, and at the same time the reactivity of the vessels to vasoconstrictor impulses is temporarily reduced. The result of a transient impairment of this element of the circulatory adjustment to change in posture is thus exemplified.

More frequently imperfect postural adaptation becomes apparent only when one or another of the various phases thereof tends to become insufficient as the circulatory strain continues. The observations of Turner, Newton and Haynes<sup>40</sup> have demonstrated that such circulatory adjustments are maintained with varying degrees of success by healthy subjects during a fifteen-minute period of quiet standing; some individuals become dizzy or actually faint after a period of eight minutes. In such circumstances stagnation of blood in the legs is demonstrable as an increase in leg volume, and pooling in the splanchnic area is suggested by the improvement in circulatory adjustment to posture which can be effected with an abdominal support (corset or bandage). Similar episodes characterized by faintness, weakness and excessive tachycardia on quiet standing are not infrequent after infectious diseases, particularly influenza, or after an individual has been confined to bed for long periods. Here both the relatively unstable vasomotor response, and the loss of support to the venous circulation afforded by the normal tone of the leg muscles impair the circulatory adjustments.

Recently several reports in the German literature have directed attention to a form of transient hypotension known as "gravity shock."<sup>41</sup> If, after strenuous exercise (sprinting), an individual stands quietly erect instead of lying down, there first ensues a fall in blood pressure and pulse rate from elevated to normal levels. This observation is analogous to that

which is customarily applied in examining a patient suspected of circulatory disease, except that it is the usual practice to put the patient through a milder form of exercise and then to place him at rest. The speed with which pulse rate and blood pressure return to normal is taken as a measure of fitness. In Mateeff's subjects there was no question of cardiovascular diseases; all were young people in athletic training. He observed that, after the pulse rate had returned to normal, if the subject remained standing, the circulatory adjustments to the erect posture tended to disintegrate: the pulse rate rose anew, the diastolic pressure rose to approach the systolic and finally both systolic and diastolic pressures fell together with the onset of circulatory collapse. Compensation was immediately restored when the horizontal posture was assumed. This, together with the fact that the development of such a condition could be prevented by bandaging the lower extremities immediately after exercise, led Mateeff to the conclusion that the fundamental cause lay in the extreme hyperemia in the leg muscles after the work. To the pooling of blood in these areas, with consequent decrease in rate of return of venous blood and secondarily deficient cardiac output, was ascribed the series of events observed.

As demonstrated by Weiss and his collaborators,<sup>7, 7a</sup> small doses of sodium nitrite, insufficient to provoke any considerable circulatory alterations with the subject supine, may yet so impair the circulatory adjustments necessary in the upright position as to lead to collapse. The effect of such amounts of nitrite is not to produce dilatation of the arterioles. These vessels maintain their tone and reactivity; they even constrict in the attempt at adjustment. Weiss *et al.* have adduced evidence to show that the primary effect of sodium nitrite is exerted upon the venous side of the circulation, impairing venous tone and resulting again in a disproportionate distribution of blood to the disadvantage of the arterial system.

All these examples of faulty circulatory adaptation to the erect posture have a common basis in the eventual stagnation of blood in the dependent portions of the capillary and venous vascular beds. As a consequence the return of venous blood to the heart is progressively reduced, its systolic discharge is lessened and, despite the increase in heart rate, the arterial

system is less and less adequately distended. Constriction of the peripheral arteries is not only unimpaired but increases, thereby maintaining and even elevating the diastolic pressure, up to the moment when collapse supervenes due to insufficient blood supply to the medullary and cerebral centers.

*Treatment.*—In such circumstances little benefit is to be anticipated from the administration of substances which enhance or maintain constriction of the peripheral elements of the arterial system. Of primary importance are measures calculated to prevent the pooling of blood in the extra-arterial portions of the vascular system and to foster the return of venous blood to the heart. The most beneficial is that which is the natural consequence of collapse: the reassumption of the horizontal position. Symptoms are dramatically relieved and the blood pressure and flow return to normal almost at once if the patient is caused to lie down. In most instances the onset of symptoms can be delayed or averted if the patient wears an inelastic abdominal support—corset, girdle or broad belt. In so far as the strength and tone of the muscles of the extremities may be improved by massage and exercise the supporting effect thereof upon the peripheral venous channels may be enhanced. Such measures are of particular value during convalescence from severe infection or prolonged illness of any sort. Sometimes the additional support of elastic stockings, temporarily applied, may be beneficial.

**Orthostatic Hypotension.**—In sharp contrast to these examples, in which circulatory adjustments to the upright position are performed but gradually become inadequate, stands the condition known as "orthostatic or postural hypotension." The distinction lies in the immediate and more or less complete failure of such adaptation as soon as the upright posture is assumed. First described by Bradbury and Eggleston,<sup>1</sup> about 30 cases of this syndrome have been reported, having the following characteristics in common: (1) immediate, pronounced and persistent fall of the systolic blood pressure, frequently as great as 50 mm. of mercury, when the patient stands; (2) a synchronous but usually smaller drop in the diastolic pressure; (3) absence or diminution of the increase in heart rate normally demonstrable upon rising to the upright position, and (4) dizziness, faintness and collapse. Additional

symptoms and signs less uniformly to be observed are: (1) orthostatic oliguria, (2) absence or suppression of sweating over part or all of the body and, perhaps, as a consequence, (3) increased distress in hot weather or hot rooms.

The observations of Ellis and Haynes,<sup>6b</sup> which include detailed examination of the circulatory dynamics in this condition, indicate that the fundamental abnormality is the failure of the reflexes which normally bring about vasoconstriction and more rapid heart rate when the patient stands. The cardiac output is not markedly changed but the blood circulates mainly through the dependent portions of the circulation. The brain receives an inadequate share of blood, and dizziness and faintness result. These circulatory phenomena, together with the hypohidrosis frequently observed, suggest some functional or anatomical impairment of the sympathetic nervous system as etiologic factors. Indeed, many of the reported instances of orthostatic hypotension have been associated with disease of the central nervous system. Similar failure of orthostatic control of blood pressure has been reported following section of anterior motor roots in the lower thoracic and lumbar regions in patients with hypertension.<sup>2</sup>

*Treatment.*—Here, too, mechanical measures such as an abdominal support or elastic stockings calculated to reduce the capacity of dependent portions of the vascular system may sometimes assist in averting the development of symptoms. But, and again in contrast with the cases of imperfect postural adjustment, in "orthostatic hypotension" drugs which promote and maintain vasoconstriction often offer considerable relief. The most valuable substance is ephedrine, the action of which is relatively prolonged. It may be given in doses of 25 to 50 mg. by mouth, commencing before the patient arises in the morning and continuing at intervals of two to four hours until the late afternoon. Too large or too frequent doses may cause unpleasant symptoms and insomnia. Recently the use of benzedrine has been reported as efficacious in orthostatic hypotension.<sup>4</sup> The fact that, in the case of both ephedrine and benzedrine, symptomatic relief may be obtained without entirely preventing the orthostatic fall in pressure suggests that the beneficial effect may be upon the brain as well as upon the peripheral vessels.

## TABULATION

	Imperfect circulatory adjustment to upright posture.	"Orthostatic hypotension."
Systolic pressure.	Maintained up to the point of collapse—then falls abruptly.	Falls immediately on standing.
Diastolic pressure.	Rises gradually to point of collapse—then falls abruptly.	Falls immediately on standing.
Heart rate.	Increases.	Remains unaltered or increases abnormally little.
Cardiac output.	Gradually decreases.	Maintained.
State of peripheral vessels.	(1) Arterioles constrict. (2) Veins, venules and probably capillaries dilate.	Arterioles fail to constrict.
Mechanism.	Pooling of blood in dependent <i>venous</i> portion of vascular bed at expense of <i>general arterial</i> blood volume.	Increase in proportion of blood in <i>all</i> dependent vessels— <i>arteries and veins</i> —at expense of that in vessels above level of the heart.

**Shock.**—Hypotension caused, at basis, by absolute reduction in volume of the circulating blood is exemplified by "shock" or "surgical shock." This is a condition of acute circulatory failure characterized by both low arterial and low venous pressures. The critical reduction of blood volume may be evoked by: (a) loss of blood by hemorrhage, (b) extravasation of blood or serum due to bruising, cutting, burning or freezing, (c) transudation of the fluid constituents of the blood through the capillaries as a result of chemical injuries which apparently effect a widespread increase in capillary permeability, or (d) by excessive fluid loss in proportion to fluid intake (dehydration) as in cases with profuse diarrhea or diabetic acidosis.

In the early stages of collapse such as follows immediately upon injury ("primary shock") there is vasodilatation but in the later phase, when circulatory failure becomes established,

the peripheral resistance is demonstrably increased and the volume flow of blood is greatly reduced. This state of the circulation, present with the patient in the horizontal position, may be likened to that described under imperfect postural adaptation above. The arteries fail to contain a proportion of the blood volume sufficient to maintain the normal blood pressure; return of venous blood is impaired by pooling or stagnation, usually in visceral venous areas, and the low venous pressure is insufficient to foster adequate systolic discharge. If the blood pressure remains low for more than a short period, fluid and electrolytes escape from vessels to the tissues and the blood volume may be still further reduced.

*Treatment.*—Except in the early (“primary”) stages adrenalin or ephedrine is without benefit. Treatment must be directed to restoring the blood volume. This may be accomplished by transfusion, and should be undertaken as soon as, or if possible before, signs of falling pressure appear.

## CLINIC OF DR. FRANK R. FORD

### THE JOHNS HOPKINS HOSPITAL

---

#### THROMBOSIS OF THE CEREBRAL ARTERIES WITH A DISCUSSION OF HEMIPLEGIA<sup>1</sup>

**Members of the Third Year Class.**—The subject of to-day's discussion is that of thrombosis of the cerebral arteries. As you know, the nervous system is nourished, just as are the other organs, by its blood supply and interruption of the blood supply results in necrosis of the tissue with softening, or as we say, infarction. The commonest neurologic syndrome resulting from thrombosis of the cerebral arteries is hemiplegia. This condition is important not only because it is so common but because many of the fundamental principles of clinical neurology are based upon the study of the phenomena observed in the course of a case of hemiplegia. These principles you will find necessary for the analysis of other neurologic syndromes which you will encounter in the future. I shall, therefore, discuss the matter in considerable detail. This patient will serve to illustrate most of the facts I wish to bring out. I may say at once that we believe that this patient has had a large lesion of vascular origin centering about the fissure of Rolando in the right hemisphere, which has destroyed the anterior and the posterior central gyri and has caused left hemiplegia and left (cortical) hemianesthesia.

This patient, a colored man of thirty-six years, was not conscious of any departure from his usual good health until some fifteen months ago. At that time he was lifting a heavy weight and suddenly felt dizzy and nauseated. Within a few minutes he became unconscious and had several convulsions involving the left arm and leg. He was brought to the hospital where he remained in a state of unconsciousness or confusion for several days. During

<sup>1</sup> This is the first of 8 clinical demonstrations which are given to the students of the third year class in neurology during the first quarter of the year.

this period his head and eyes were turned to the right side and his left arm and leg were flaccid and immobile. The left cheek moved in and out during respiration showing that even the facial muscles shared in the loss of tone. The tendon reflexes were absent on the left for several days. His bladder was distended and had to be emptied by catheter. The left hand was warm and dry during this period and within a short time began to show slight edema. His blood pressure was elevated to 210/115 and there were evidences of sclerosis of the peripheral and the retinal arteries. The Wassermann test was negative in the blood and spinal fluid.

On the fifth day the patient began to regain consciousness and was able to cooperate for a few minutes during the examination. It was found that the patient could not move the left arm or leg. The left side of the mouth showed very little movement but he was able to close the eyelid and wrinkle the forehead almost as well on one side as the other. The chest moved freely on both sides but it was found that the movements were somewhat smaller on the left side than on the right. This was true of spontaneous breathing as well as voluntary breathing. The head could be lifted from the pillow and rotated fairly well to either side. The eyes still showed a tendency to deviate to the right and the patient could not move them to the left beyond the midline. Articulation was indistinct. There was some difficulty in emptying the bladder. The tendon reflexes were present on both sides and about equally active. The abdominal reflexes were absent on the left. Sensibility seemed to be much diminished over the entire left side of the body, but it was impossible to make a satisfactory examination owing to the patient's diminished power of attention.

The patient's condition slowly improved and about four weeks after the onset of the illness he began to regain power in the left leg. He was permitted to return home. Convulsive seizures involving only the left side continued to occur at intervals of two or three months. His blood pressure remained about 200/115.

A complete neurologic examination was made in the out-patient department seven months after the illness, which revealed the same condition which the patient presents today. You can see that the patient's eyes are moved freely in all directions and that his face is almost symmetrical. There is, however, a slight increase of muscle tone on the left side of the face which is shown by moderate deepening of the nasolabial fold. Now, when the patient shows his teeth, you can see that the left side of the mouth moves almost as well as the right side, although close observation will reveal a slight delay in the movement and a slight reduction of the excursion. When the patient laughs, however, the movement of the left side of the mouth is actually greater than that of the right side. The functions of the other cranial nerves are preserved. His tongue is protruded in the midline and can be moved easily to either side, although in some patients suffering from this same condition the tongue may deviate a bit to the side of the paralysis. You have noticed, no doubt, that the patient's left arm is held in a peculiar position. It is adducted and internally rotated at the shoulder, flexed to almost 90 degrees at the elbow, pronated in the forearm, and flexed at the wrist and finger joints. The leg, on the contrary, is adducted and extended at all joints. You will notice that

when I try to extend the arm I meet with considerable resistance, but flexion is much easier. The arm is held in this position as a result of increase of muscle tone in certain groups of muscles. This statement also applies to the leg which can be passively flexed only by the exertion of a great deal of strength but may be extended quite easily. As I flex the leg there is strong resistance to the movement at first, but as the movement is continued the resistance melts away so that the leg can be flexed with little effort. You see now that the leg is maintaining the position of flexion which I imposed upon it, although I have withdrawn my hand. As I try to extend it now I meet with some little resistance. The muscles, therefore, have a property which might be termed *plasticity*. Stimulation of the sole of the foot will relax the extensor tone at once and the leg is then easily flexed. This peculiar type of rigidity is properly termed *spasticity*, a condition which has been precisely defined by Walshe. The patient has never recovered the proper use of his left arm and leg and I will now show you the extent of his disability. You will note that he can walk, but the left leg is not moved normally. The leg is not fully flexed at the knee as it is brought forward and the toes are not lifted from the floor. The leg is advanced chiefly by rotating the pelvis, using the right leg as a pivot. To clear the left toes, which would scrape the floor, he swings the foot in a semicircle. The leg is used somewhat as an artificial leg might be used, that is, as a prop. The patient can grasp my hand with some force, but you will notice when he makes a maximum effort, the elbow is somewhat flexed, the forearm pronated and the arm abducted at the shoulder. He cannot squeeze my hand without making these movements at the same time. He cannot flex one finger without flexing all the other fingers as well as the thumb. When he tries to flex the elbow, the arm is also abducted a bit and the fingers close. In the same way he cannot abduct the arm at the shoulder without flexion of the elbow and fingers. When I ask the patient to extend the fingers, there is very little movement of the fingers, but there is some extension at the elbow and adduction at the shoulder. When he makes one of these movements the others invariably occur. I shall now place him on the couch in order to examine the leg. When he tries to flex the hip, which he does with great difficulty, there is also flexion of the knees and dorsiflexion of the foot. The attempt to flex the knee causes flexion of the hip and dorsiflexion of the foot. He cannot move the foot or the toes without flexing the hip and knee at the same time. The patient has therefore lost the ability to perform isolated movements involving single muscle groups, and such movements as he can perform are always mass movements. Foerster terms such mass movements *synergies*. The chest still moves less on the left side than on the right. It is impossible for you to see this difference from the benches, and it is really very slight. We have made many graphic records of his chest movements, however, and you may take my word for it. The patient can now empty his bladder with very little difficulty, but he complains of frequency. It has been shown in similar cases of hemiplegia that the bladder is small and that the stretch reflex is increased. The tendon reflexes are all much exaggerated in the left arm and leg. The activity of the tendon reflexes corresponds to the distribution of tone in the muscles. Thus, the biceps reflex is more active than the triceps, the knee jerk is greater than the hamstring reflex. The

plantar reaction is a typical Babinski reflex. You see that the great toe is slowly extended (dorsiflexed) in a well-sustained movement and at the same time the small toes are spread apart and also somewhat extended. There is a well-sustained ankle clonus. The abdominal reflex has now returned but is easily exhausted by a few strokes.

The patient is conscious that sensibility is deficient over the left side of the body, especially in the left hand and foot. You will note, however, that he can distinguish the sharp end of the pin from the dull end. In the same way he can distinguish heat and cold. These modalities of sensibility are not normal but they are not lost. Now I take the patient's left forefinger and move it up and down. The patient cannot recognize these movements even when they are relatively gross. He cannot find the left hand with the right when his eyes are closed. In the same way he cannot localize a touch on the left arm or leg and cannot guess whether I am applying both points of a compass or just one point.

The left hand is now cold and rather moist. You will recall that during the early part of his illness the left hand was warm and dry. The edema which was present at first has now disappeared.

These facts will be somewhat clearer if I offer an interpretation. You will recall that the patient's illness began with a convulsion confined to the left side of the body. Movements of the left side of the body are represented in the motor cortex of the right hemisphere. Sudden interruption of the circulation caused anoxemia which for a time caused excitation. As a result, the functions residing in the affected area were discharged in an explosive fashion and a convulsion took place. We classify convulsive seizures of all types among the symptoms due to *discharge of function*. Such phenomena are not peculiar to the motor cortex. Discharges involving numerous other cortical areas are well known. When the postcentral convolution is affected, the patient experiences paresthesias over the opposite side of the body. Olfactory and gustatory hallucinations occur in discharges involving the uncinate gyrus. Visual hallucinations of a crude nature are associated with discharges in the occipital cortex and more elaborate visual phenomena with discharges of cortical areas in the temporal lobes. Even the lower centers of the brain stem and spinal cord are capable of discharge.

After the convulsion the patient remained unconscious for several days. His left arm and leg were quite flaccid and devoid of tone; the tendon reflexes were abolished on that side. As you know, the tendon reflexes are dependent upon the spinal

reflex arcs. Consciousness does not reside in any sharply localized part of the brain. Evidently the sudden insult to the brain resulted in transient but widespread disturbances which affected not only the brain but the spinal segments as well. We may attribute such symptoms to neurologic *shock* for lack of a better term. Such symptoms do not occur in cases of slowly progressive hemiplegia due to tumors of the brain.

After consciousness was regained it was found that there was loss of isolated voluntary movements of the left arm and leg and also disturbances of sensibility over the left side of the body, involving chiefly sense of passive movement, sense of position, tactile localization and two-point sense. It is well established that isolated volitional movements are dependent upon the integrity of the motor cortex and that the type of anesthesia with which we are dealing indicates injury to the postcentral convolution or to its projection pathways. The patient, therefore, suffers from *loss of function* of both the motor and the sensory cortex.

Several weeks after the onset of the illness, the patient's condition began to change. The affected extremities grew spastic and began to assume a peculiar posture with the arm in flexion and the leg in extension. The tendon reflexes became grossly exaggerated. Plantar stimulation caused dorsiflexion of the great toe. Such signs cannot be due to loss of function for they are obviously due to excessive and uncontrolled activity of some part of the nervous system. It is customary to term them symptoms due to *release of function*. In the analysis of release phenomena we must always ask ourselves two questions: (1) what structures are released? and (2) what structures are destroyed? There is abundant evidence derived from clinical observation and from experimental investigation to show that these particular signs are due to release from cortical control of the spinal reflex arcs and of certain structures lying within the hindbrain which many observers identify with the vestibular nuclei. These structures seem to be important elements in the complex nervous mechanism which maintains muscle tone and posture and their release results in the development of the peculiar posture observed in hemiplegia. Walshe has shown that this hemiplegic

posture is an exaggeration of our normal standing posture. From the physiologic point of view, hemiplegia has a close relationship to decerebrate rigidity in the experimental animal. The gross exaggeration of the tendon reflexes is regarded as evidence of loss of inhibition of the spinal reflex arcs. Ankle clonus is merely a series of tendon reflexes. Study of electromyographic records indicates that each beat of the clonus is associated with a single diphasic action current in the muscle such as occurs in a tendon reflex. Sudden pressure on the sole of the foot stretches the extensors of the ankle which contract just as they do when the tendo achillis is struck with the percussion hammer. The foot is therefore abruptly extended and the dorsiflexors are stretched, resulting in a reflex contraction of the flexors. One reflex thus provokes the next reflex. The plantar reflex also requires some comment. Babinski was the first to show that in disease of the pyramidal tract, stimulation of the outer aspect of the sole of the foot causes dorsiflexion of the great toe and abduction of the small toes. Walshe has shown that this movement is merely a part of a more extensive movement of triple flexion by which the foot is withdrawn from potentially injurious stimuli. It may, therefore, be regarded as a spinal reflex of defense. The reflex is best elicited from the sole of the foot but may be produced by strong stimuli applied to any part of the lower limb or even to the abdomen in certain cases. Although the Babinski response often offers some difficulty in interpretation, the existence of a typical reaction constitutes the most reliable clinical evidence of disease of the pyramidal tract. I must now discuss the second question. What structures must be destroyed to produce spasticity? Do the corticospinal fibers which activate the spinal motor neurons in volitional activity also convey inhibitory impulses to these neurons? This problem is still a subject of debate, and I cannot give you a definite answer. The neurons which give rise to the fibers of the pyramidal tract are found in the cortex just anterior to the fissure of Rolando. This region has been termed area 4 by Brodmann. Just anterior to area 4 is another histologically defined area termed by Brodmann area 6. John Fulton and his collaborators claim, chiefly on the basis of experimental work, that lesions in area 6 cause spasticity with little or no

paralysis and that lesions in area 4 cause paralysis without increase of muscular tone. Typical hemiplegia with spasticity results when both of these areas or their projection pathways are destroyed. This view is strongly opposed by Walshe for a variety of reasons. He cites several cases in man, in which careful excision of area 4 has been performed with resulting hemiplegia and spasticity. Foerster, who has had an unrivaled experience in cortical excision in man, also states that ablation of area 4 alone causes typical hemiplegia with spasticity, and that ablation of area 6 a  $\beta$ , which constitutes the larger part of area 6, is associated with no demonstrable signs or symptoms whatever.

The improvement in the patient's condition during convalescence requires some consideration. It is a firmly established teaching that neurons of the central nervous system cannot regenerate. Destruction of a neural pathway must, therefore, result in irreparable damage. Nevertheless, the patient improved to some extent. He regained the power to move the extremities, to empty his bladder, and to walk. It is customary to divide the period of improvement into two stages. During the first stage, which lasts only a few days or weeks, improvement is rather rapid and may be due chiefly to the disappearance of shock. The second stage lasts for a year or more and improvement during this period is more gradual. Hughlings Jackson has discussed this tendency to improvement following injuries to the nervous system under the term of *compensation*. According to Jackson, those structures which contribute to the return of motility can produce only those movements which they produced under normal conditions before the lesion developed. Jackson believed that the movements of each side of the body are represented in both hemispheres although to different degrees. Isolated movements of the extremities are represented almost entirely in the contralateral motor cortex and to a minimal degree in the homolateral cortex. Consequently when the contralateral motor cortex is destroyed, as it is in the present case, such movements can be regained to only a limited extent and then after long training. Other movements are affected to varying degrees. Many years ago Broadbent pointed out that movements are preserved in hemiplegia in proportion to their bilaterality. Strictly

unilateral movements, such as isolated movements of the extremities, are completely lost and are never regained; movements which are sometimes bilateral and sometimes unilateral, such as those of the shoulders and hips, are regained to a large extent; and movements which are always bilateral, such as those of the eyes, larynx, pharynx, chest, abdomen and spine, are never more than slightly affected. Movements of the last type are of course represented almost equally in the two hemispheres. The study of cases of bilateral hemiplegia lends strong support to the theory that certain movements have bilateral representation in the cortex. Bilateral lesions in the motor cortex cause not only paralysis of the extremities, as in hemiplegia, but also pseudobulbar palsy, in which paralysis of the larynx, pharynx, jaws and face may occur. Moreover, there is a striking weakness of all the muscles of the trunk.

The mass movements of the affected extremities, termed synergies by Foerster, arise, he claims, in certain areas in the contralateral cortex which have escaped injury. These are area 6 of Brodmann which lies in the superior frontal convolution, area 5 in the superior parietal convolution, and area 22 in the superior temporal convolution. These are not connected with the spinal cord by way of the pyramidal tracts but influence the spinal cord indirectly by way of lower centers. Foerster states that electrical stimulation of these areas when they are exposed at operation causes the same mass movements which the hemiplegic patient produces voluntarily. Moreover, spontaneous discharges arising in such areas cause convulsions in which mass movements occur. When these areas are excised in hemiplegic patients, there is a great reduction in the remaining motility.

You will remember that during the first few days of this patient's illness there was retention of urine and since then there has been mild frequency of urination. Langworthy has shown that in such cases the bladder is small and that the stretch reflex is increased. It will not be amiss, therefore, to say a few words about the innervation of the bladder. As you know, the bladder receives a segmental nerve supply from the lumbar and sacral segments of the cord. It has been shown that there is also a mechanism located in the midbrain which exerts an important effect on the tone of the bladder

musculature. Voluntary control of the bladder, however, is vested in the upper part of the motor cortex on the mesial surface of the hemisphere. This representation is of course bilateral, and unilateral lesions never cause more than mild or transient disorders of bladder function. The initial retention in hemiplegia is probably due to shock involving the segmental mechanisms, whereas the frequency which appears later is probably to be attributed to release of the spinal and midbrain mechanisms. The behavior of the smooth muscle of the bladder, therefore, is in many ways similar to that of the striated muscle of the extremities.

The vasomotor disturbances present in the affected hand deserve some comment. Such conditions are not always demonstrable and when present are not always the same. However, the conditions observed in this patient are, in my experience, both common and characteristic. In most cases the hand is warm, dry, pink and slightly edematous during the first few days after the onset, and subsequently it becomes cold, wet and slightly cyanotic. In a small percentage of cases there is massive edema and outspoken elevation of temperature in the affected extremities during the first stage of the illness. The temperature may be elevated more than  $1^{\circ}$  C. The interpretation of such changes is still uncertain. One might assume that in the initial stage we are dealing with the effects of shock upon the segmental autonomic reflexes which control sweating and vasomotor reactions and that subsequently the reverse effects are caused by release of the same reflexes. This cannot be regarded as more than an attractive hypothesis at present.

The sensory disturbances must now be taken up. As a result of the investigations of Henry Head and of Gordon Holmes, it is known that the cerebral cortex is not necessary for the appreciation of crude sensations of touch, pain, heat and cold. The thalamus is capable of subserving such modalities of sensibility. The cortex, however, is necessary for the recognition of passive movements, of position, of localization of stimuli and for the appreciation of differences and degrees of tactile and thermal stimuli. A little reflection will convince you that the function of the sensory cortex is that of interpretation, synthesis and analysis of simple sensations.

This patient shows loss of these functions and he may, therefore, be said to have *cortical anesthesia*. It is important to keep in mind that special tests are required for the demonstration of anesthesia of this type, for hemianesthesia is just as significant of cerebral damage as is hemiplegia and may be overlooked if proper tests are not applied. The disturbances of tactile and of thermal sensibility are of such a nature that quantitative tests must be applied to demonstrate them. Such tests are therefore not suitable for practical clinical neurology. The tests for appreciation of position and passive movement and the compass test for two-point sensibility are so simple that they should be employed as a routine in every examination of a patient suffering from disease of the nervous system.

Thrombosis of the cerebral arteries may result from a large number of conditions. In general, it may be said that it may be the result of any change in the properties of the blood which favors clotting or of any disease of the arteries. The possible causes are, therefore, almost innumerable. In the vast majority of cases, however, the patient is suffering from cerebral arteriosclerosis with or without hypertension. It must be borne in mind that the degree of sclerosis of the cerebral arteries is not always equal to that of the peripheral or retinal arteries. We have seen advanced changes in the cerebral arteries in patients whose peripheral arteries were soft. Moreover, arteriosclerosis is not confined to elderly subjects, for young adults and, in rare cases, even children may develop the same changes. The second commonest cause of thrombosis of the cerebral arteries is syphilis. We should always investigate the possibility of syphilis whenever we find evidences of cerebral vascular disease. Certain acute infectious diseases, such as typhoid fever, scarlet fever, diphtheria and numerous others, may cause lesions in the arteries which occasionally lead to thrombosis. In some cases proliferation of the intima of a cerebral artery leads finally to occlusion of the lumen, giving rise to symptoms identical with those of thrombosis. Embolism is another possible cause of cerebral vascular occlusion. As a rule cerebral emboli arise as a result of endocarditis or of detachment of bits of mural thrombi from seriously diseased hearts. Rupture of cerebral arteries with hemorrhage into the brain is not uncommon, but is probably less frequent than

thrombosis. It is a result of hypertension in most cases. As a rule hemorrhage is associated with a greater degree of shock at the onset and, moreover, leads to the development of increased intracranial pressure in many cases. The spinal fluid may contain blood. The mortality is much higher in cases of intracranial hemorrhage than in cases of cerebral softening due to thrombosis.

The study of cases of thrombosis of the cerebral arteries has led to the accumulation of a great deal of information about the distribution of the arteries and about the functions of various parts of the brain; for the occlusion of any given artery produces a lesion of almost constant extent and an almost constant group of symptoms. Foix and his collaborators have taken a leading part in this work. It is impossible to review this whole field in the short time at my disposal, but I shall mention the more important syndromes in brief, deferring a more complete discussion to another time.

The chief arteries which supply the brain are the anterior, middle and posterior cerebral arteries. The two anterior cerebral arteries are united by the anterior communicating artery, and the middle cerebral arteries are joined to the posterior cerebral arteries by the posterior communicating arteries. The posterior cerebral arteries are formed by the bifurcation of the basilar artery, which is formed by the union of the vertebral arteries. Thus an unbroken arterial channel is formed under the base of the brain which is called the circle of Willis.

The anterior cerebral artery supplies the cortex covering the mesial surface of the hemisphere from the frontal pole to the parieto-occipital fissure. This area includes the motor and sensory representation of the leg. The corpus callosum is also included. This artery further supplies the anterior part of the superior frontal convolution and the inferior surface of the frontal lobe. It sends penetrating branches into the anterior limb of the internal capsule and the anterior portions of the lenticular and caudate nuclei. Thrombosis of the cortical branches of this artery causes paralysis with spasticity of the contralateral leg, with or without cortical anesthesia. In many cases some degree of motor apraxia may be demonstrated as a result of softening of the corpus callosum. You are probably not familiar with the term apraxia. It may be defined as an

inability to perform purposive movements in the absence of paralysis, incoordination or dementia. Regardless of the side of the lesion, the apraxia is always in the left arm, or, more properly, in the subordinate arm. In some cases the patient's hand will always grasp objects placed in it, in such a way that it is difficult to relax the grasp. This is termed forced grasping. It has been shown by Walshe that this is due to a stretch reflex and is associated with lesions in the superior frontal convolution. It is always found on the side contralateral to the lesion. If the penetrating branches of the anterior cerebral artery are occluded, we may have hemiplegia on the opposite side.

The middle cerebral artery supplies the entire lateral surface of the hemisphere except for the anterior part of the superior frontal convolution and the inferior temporal and temporo-occipital gyri. It also sends penetrating branches which supply the internal capsule except for the anterior limb and the posterior parts of the lenticular and caudate nuclei. Thrombosis of the cortical branches may cause paralysis with spasticity of the contralateral arm and side of face when the precentral convolution is involved, cortical anesthesia confined to the arm when the postcentral convolution is softened and hemianopia when the optic radiation is involved in its passage through the temporal lobe. When the lesion is in the left hemisphere, in right-handed subjects, there may be either motor aphasia, sensory aphasia or both. Aphasia is a disorder of speech comparable to apraxia. In motor aphasia the ability to express oneself is chiefly affected and in sensory aphasia it is the receptive functions which are chiefly disturbed. In general, lesions lying anteriorly in the inferior frontal convolution are most apt to interfere with motor speech and lesions lying posteriorly in the superior temporal and inferior parietal lobes are most frequently associated with sensory aphasia. Bilateral apraxia may also occur when the cortex is involved in the region of the angular and supra-marginal gyri. If the penetrating branches are occluded, there will be complete hemiplegia, hemianesthesia, and hemianopia. Complete occlusion of the artery is almost always fatal within a short time for a very large part of the hemisphere is softened. The posterior cerebral artery supplies the occipital lobe,

the inferior surface of the temporal lobe, most of the thalamus and the midbrain. Thrombosis of the cortical branches of the posterior cerebral artery causes hemianopia and, if the lesion is on the left, alexia or inability to read. Occlusion of the penetrating branches may cause the classical thalamic syndrome of Dejerine and Roussy. Thrombosis of the small branches supplying the midbrain may cause a variety of symptoms including Weber's and Benedict's syndromes and cerebellar ataxia.

Thrombosis of the basilar artery is probably incompatible with life, but several interesting syndromes result from occlusion of branches of this artery. Softenings are found in the pons which cause hemiplegia on the opposite side and often homolateral paralysis of the sixth or seventh nerve. Cerebellar ataxia may result from injury to the brachium pontis.

Occlusion of the vertebral artery causes contralateral hemiplegia without involvement of the face and analgesia as well as thermanesthesia over the homolateral half of the face. Occlusion of one of its branches, namely the posterior inferior cerebellar artery, causes a very rich and interesting syndrome. There is paralysis of the homolateral side of the soft palate and larynx, anesthesia and thermanesthesia over the homolateral side of the face, analgesia as well as thermanesthesia over the contralateral side of the body below the face, cerebellar ataxia of the homolateral arm, nystagmus, vertigo and falling to the same side, and sometimes, myosis of the homolateral pupil and drooping of the homolateral eyelid. These symptoms are due to a softening in the lateral part of the medulla involving the nucleus ambiguus, the descending roots of the fifth and vestibular nuclei, the restiform body and the spinothalamic tract.

The treatment of thrombosis of the cerebral arteries is very unsatisfactory. Once the damage has been done it cannot be repaired. We are therefore forced to employ merely symptomatic therapy. During the stage of unconsciousness, we must support the circulation, administer proper amount of fluids and care for the bladder properly. Convulsions may be controlled by luminal or other sedatives. During convalescence, hemiplegia patients should have massage and passive movements to prevent contractures of the muscles and changes

in the joints. Later, they should have exercises and in certain cases orthopedic operations are indicated to prevent or cure deformities. If syphilis is present, or any other disease for which we have effective treatment, proper remedies must be applied, but we should not expect to modify the patient's symptoms by this means. At most, we may hope to prevent further damage to the nervous system.

## CLINIC OF DR. MAXWELL M. WINTROBE

### THE JOHNS HOPKINS HOSPITAL

---

#### THE APPLICATION AND INTERPRETATION OF THE BLOOD SEDIMENTATION TEST IN CLINICAL MEDICINE

IN little more than a decade the blood sedimentation test has attained widespread use. For this there are two reasons. One is the simplicity of the test; the other is its applicability to all phases of medicine.

The principle of the test is extremely simple. The blood is essentially a suspension of corpuscles in plasma. For the sedimentation test, blood is mixed with an anticoagulant, and the stability of the suspension is measured by putting some blood into a narrow tube which stands in a vertical position. The sedimentation of the red corpuscles can then be observed.

Although Fåhræus, a Swede, is responsible for the introduction of the sedimentation test into modern medicine, it is in a sense as old as the theory of the four humors. When blood was withdrawn from a healthy person, it was observed that it clotted and formed two portions, the serum and the clot. On the other hand, when blood was withdrawn from a diseased person, sedimentation being more rapid, separation of several layers occurred before clotting permitted no further change to take place. In this blood, four portions could be distinguished: (1) the uppermost yellowish fluid, formed by the blood serum ("cholera" or "yellow bile"); (2) a grayish-white layer of fibrin in the upper portion of the clot ("phlegma" or "mucus"); (3) a bright red layer made up chiefly of red corpuscles ("sanguis"); and (4) a dark red, almost black portion made up of red corpuscles deprived of oxygen ("melancholia" or "black bile"). In the medical philosophy of the ancient Greeks, ill health was thought to be due to the failure

of these four "humors" to mix. In the medical thought of later years the phlegma received chief attention and as the "crusta inflammatoria," "buffy coat" or "size" was thought to be the cause of disease. It was to rid the body of this supposedly harmful substance that venesection was performed.

Fåhræus' discovery of the value of the sedimentation test was quite accidental. In his search for an early test for pregnancy he found that the rate of sedimentation of the red corpuscles is increased not only in pregnancy but also in many diseases.

#### THE NATURE OF THE SEDIMENTATION PHENOMENON

Little is known about the true nature of the sedimentation phenomenon. Fåhræus pointed out that the suspension stability of the blood is determined by the radius of the suspended particles. Variations in the latter depend on differences in the degree of aggregation of the red corpuscles, with resulting formation of larger or smaller particles. In bloods in which sedimentation is rapid large aggregates are formed.

The cause of the increased aggregation or rouleaux formation of the corpuscles is not known. It appears to be some factor present chiefly in the plasma, for sedimentation is more rapid in plasma than in serum. There is a close correlation between the quantity of plasma fibrinogen and sedimentation rate, and there is some correlation between the amount of plasma globulin and the rate of sedimentation. Yet it is not correct to assume, as many writers have done, that the increased rate is therefore *due* to increases in plasma fibrinogen or globulin. The real causative factor has not yet been demonstrated.

#### METHODS FOR DETERMINING SEDIMENTATION RATE

Numerous methods have been devised for determination of sedimentation rate. Actually these are all modifications of two principal methods. The blood, to which an anticoagulant has been added, is placed in a narrow tube which is fixed in a vertical position. Then either the *time* required for the upper level of sedimenting corpuscles to fall a specified distance is measured (Linzenmeyer method), or the *distance* the corpuscles fall in a specified interval of time is noted (Westergren

method). The latter method is more generally used because it is so simple to fill the sedimentation tube and then to pay no further attention to it until the time chosen to read it has elapsed.

Some investigators recommend that readings be made at short, usually five-minute, intervals. When this is done and the readings are recorded on a chart, every variation from

Fig. 107.—Sedimentation curves in the normal and in various disorders: A, normal; B, mild tonsillitis; C, mitral insufficiency without active rheumatic infection; D, chronic bilateral salpingitis and endocervicitis; E, bronchitis and bronchiectasis; F, acute pharyngitis, laryngitis and bronchitis. Both the "corrected" and "uncorrected" sedimentation rates are recorded in the last column.

an almost horizontal line to one which quickly falls in a vertical direction, may be encountered (Fig. 107). It can then be observed that in the process of sedimentation there are three phases: namely: (1) a preliminary period during which aggregation of the red corpuscles takes place, (2) a period of rapid fall, and finally (3) the phase of packing when the corpuscular masses, piling on one another, slow up the rate of sedimentation.

It is the phase of rapid fall which is thought to be of chief significance in the sedimentation test and for this reason charting of the changes which occur at five- or ten-minute intervals has been recommended. Actually, however, the distance which the corpuscles have fallen at the end of one hour is accounted for chiefly by this phase of rapid fall. Consequently, in the opinion of most workers, it is quite adequate to make only one reading, at the end of one hour. By doing this, the simplicity of the sedimentation test is preserved and yet adequate information is gained.

In the interpretation of the sedimentation test it is important to make certain that the test has been properly carried out, because a number of simple variations from the standard technic may cause delay or increase in the rate of fall of the corpuscles. Thus, if an excess of anticoagulant is used, the rate may be delayed. If the tube is allowed to stand even at an angle of 87 degrees rather than 90 degrees, the speed of sedimentation is markedly accelerated. It is also important to use tubes of uniform bore and length. Again, blood should be used for the sedimentation test within four hours of its withdrawal from the patient, as otherwise the rate may be less than that in freshly drawn blood. Furthermore, excessive cold will slow sedimentation while heat causes acceleration.

In order to ensure uniformity of results, we follow a standardized technic<sup>11</sup> using the hematocrit devised by the writer as the sedimentation tube (Fig. 108).

"1. Five cc. of venous blood is collected by means of a dry syringe and needle and mixed in a small bottle containing 4 mg. solid potassium oxalate and 6 mg. solid ammonium oxalate. This concentration of oxalate does not alter the sedimentation rate as compared with that of blood collected in heparin. Less than 1 cc. of blood is needed for the sedimentation test. The remainder can be used for other blood examinations.

"2. The blood so collected should be used for the determination of sedimentation rate within four hours of its time of collection. Further delay may be associated with increased suspension stability of the blood.

"3. The hematocrit is filled with blood to the 10 cm. mark.

The upper level of sedimenting corpuscles may be read at frequent intervals, or more simply, a single reading may be made at the end of one hour.

"4. Since sedimentation rate increases with increasing temperature, the sedimentation test should be carried out at a temperature not less than  $22^{\circ}$  nor greater than  $27^{\circ}$  C. Within this range variations resulting from differences in tem-

Fig 108.—Sedimentation of blood in hematocrit. A, Sedimentation of the blood of a normal male adult at the end of one hour; B, sedimentation of the blood of a normal female; C, the same sample of blood as in B, following centrifugation to secure complete packing of corpuscles; D, E and F represent the blood of 3 patients with slight, moderate, and marked increases in sedimentation velocity (Wintrobe, *International Clin.*, J. B. Lippincott Co., 1936, vol II, 46th series, p. 34.)

perature are small. If the blood used has previously been kept in a refrigerator it should first be permitted to attain the above temperature before being used.

"5. The hematocrit should be kept in an exact vertical position during the sedimentation of the blood corpuscles, for when the instrument stands at an angle of even  $3^{\circ}$  from the vertical, significant acceleration of sedimentation takes place.

"6. After sedimentation rate has been determined, the

hematocrit containing the blood should be centrifugalized and volume of packed red cells determined. The sedimentation rate may then be corrected for alterations due to anemia."

It has been repeatedly shown that variations in the quantity of sedimenting red corpuscles cause differences in sedimen-

Fig. 109.—The logarithmic curve on which this chart is based is heavily outlined. The mean normal volume of packed red cells for men (47 cc.) and for women (42 cc.) are also heavily outlined and the range of normal sedimentation is represented by solid and open columns for each sex, respectively. For correcting sedimentation rate, find on the chart the horizontal line corresponding to the sedimentation rate for the patient; find also the vertical line corresponding to the volume of packed red cells in the patient's blood. Select the curve lying nearest to the point of junction of the horizontal and the vertical line and follow this curve to the normal line for the sex of the patient. The horizontal line corresponding to this last point of juncture gives the corrected sedimentation rate. A simpler method of correction is to correct all values to the volume of packed red cells normal for the male (47 cc.). Thus a single standard of normal can be used for both sexes. See text. (Wintrobe and Landsberg in *Amer. Jour. Med. Sci.*, 189: 102 [Jan.], 1935)

tation rate. A decrease in their number, as in anemia, permits a more rapid rate of fall, whereas when they are increased above the normal, practically no sedimentation occurs. Such alterations in sedimentation rate due to differences in the

quantity of corpuscles may be allowed for by the use of the chart shown in Fig. 109. .

There are several reasons why the hematocrit should be used for the sedimentation test. The chief one is that the quantity of corpuscles may easily be determined in the same tube by simply centrifugalizing (3000 revolutions per minute, for thirty minutes) after sedimentation has been recorded. As a routine procedure this is useful not only in simplifying the correction of sedimentation rate, but it is a quick and accurate means of discovering whether the patient has anemia or polycythemia. Furthermore, from the thickness of the layer of leukocytes and platelets which is found above the layer of packed red corpuscles, one may gauge roughly the quantity of these corpuscles in the blood. Finally, the icterus index may be measured by comparing the color of the plasma in the hematocrit with the color of a series of tubes containing potassium dichromate solution in various dilutions.<sup>9</sup>

In infants and young children, when venipuncture is not practical, a modification of the above method may be employed. The heel or finger is punctured deeply enough to secure a free flow of blood. With a capillary pipet blood is transferred quickly in successive small amounts to a small test tube containing approximately one-tenth the amount of oxalate mixture used for 5 cc. venous blood. Thorough mixing of blood and anticoagulant must be secured. After a little more than 0.5 cc. of blood has been obtained, it is transferred to the hematocrit, which is filled only half way. Sedimentation is then recorded in the usual manner, following which the blood is centrifugalized. To obtain the volume of packed red cells per 100 cc. of blood, the reading must, of course, be multiplied by two.

#### NORMAL SEDIMENTATION RATE. PHYSIOLOGIC VARIATIONS

The normal sedimentation rate differs according to the method used. It is therefore essential that a standard procedure be followed and the normal for the method employed be known.

In *health* a slight interindividual variation in sedimentation rate occurs, and there is also a distinct difference in rate between the sexes. Thus, when the technic described was em-

ployed, the sedimentation rate in healthy men averaged 3.7 mm. at the end of one hour (0 to 6.5 mm. in 86 per cent of the subjects) while in healthy women it averaged 9.6 mm. (0 to 15 mm. in 86 per cent). This difference, however, is largely accounted for by the quantitative difference in corpuscles in the blood of men and women. When these sedimentation rates in 136 men and in 100 women were "corrected" to a volume of packed red cells of 47 cc. per 100 cc. of blood, the sedimentation rate in 72 per cent of the men and women ranged between 0 and 6 mm. at the end of one hour, and in an additional 16 per cent, it was 7 to 10 mm. These values may be considered the limits of normal.

As has already been mentioned, sedimentation is accelerated during *pregnancy*. From about the tenth or twelfth week there is usually a gradual increase in rate which does not return to normal until the third or fourth week postpartum. A slight fluctuation of the rate of sedimentation occurs in relation to the menstrual cycle, but the changes are so small that, from a clinical standpoint, they are of no significance. Other factors, such as the ingestion of food, or short violent exercise, are of no importance.

#### VARIATIONS IN SEDIMENTATION RATE IN DISEASE

Methods for the determination of sedimentation rates and the variations under physiologic conditions have been discussed in some detail because, unless the technician performing the test and the physician interpreting the results are fully cognizant of these details, important errors may be introduced and the results in consequence become misleading. When the method is understood, however, the test becomes an extremely valuable aid in almost all phases of clinical medicine.

In the interpretation of the sedimentation test it is essential to bear in mind that it is a nonspecific reaction which may be compared with the temperature chart, the pulse rate and the leukocyte count, in that it gives information of a general character. It is in fact less specific than the leukocyte count when the differential examination of the white corpuscles is included under the latter head, for then the leukocyte count may offer a clue to the nature of the disease.

It may be asked what purpose there is in the sedimentation

test if it affords information of the same type as the temperature and pulse record and the leukocyte count. In answer it may be pointed out that in many disorders and even in certain stages of febrile diseases, there may be no fever or tachycardia and the leukocyte and differential counts may be essentially normal; yet in many of these instances the sedimentation rate may be increased. The sedimentation test is, thus, complementary to these valuable clinical tools. Like them it is a *measure of the presence and intensity of morbid processes within the body.*

Sometimes an increased sedimentation rate is found and nothing can be discovered to explain this increase. So little is still understood about the exact nature of the sedimentation reaction that a complete definition of the circumstances under which alterations in sedimentation rate may be expected to occur cannot be given. Yet, if the sedimentation rate in any patient is found repeatedly to be increased, the careful physician will seek to discover the cause.

The sedimentation rate is increased in all *acute general infections*. The degree of increase tends to parallel the severity of the infection. Although an accelerated rate generally does not appear as soon as elevation of temperature, the abnormal rate subsides more slowly and for this reason it may serve as a guide to the condition of the morbid process after fever and tachycardia have disappeared. When complications develop, the sedimentation rate is further increased and this fact may serve to indicate the onset of a complication before its nature and site have been determined. In *localized acute inflammatory conditions*, variations in sedimentation rate depend on the nature and severity of the morbid process. In *simple catarrhal inflammation*, such as acute catarrhal appendicitis, simple rhinitis and bronchitis, the sedimentation rate tends to be normal whereas in *localized acute suppurations*, such as pelvic inflammatory disease, suppurative mastoiditis or sinusitis, there is a pronounced acceleration of sedimentation. In *chronic localized infections* the rate varies with the extent and nature of the infection, normal values often being found in chronic tonsillitis, whereas increased rates occur in chronic bronchitis, tuberculosis, syphilis, nephritis and liver abscess. Generally speaking, sedimentation rate tends to be normal in

uninfected benign *new growths* whereas it may be increased when a malignant tumor is present. The latter, however, is not necessarily the case and the factors which probably determine whether the sedimentation rate is accelerated or not include the anatomic character of the growth, its vascularity, the tendency to break down, the degree of resorption of tumor tissue, the degree of reactive inflammation, and the location as well as the presence of metastases.<sup>4</sup>

### SEDIMENTATION RATES IN VARIOUS DISORDERS

The sedimentation reaction has been demonstrated to be of particular value in following the course of a number of disorders. It will be of interest to discuss these in detail for they illustrate the peculiar advantages of this test.

That the sedimentation test is extremely valuable in *phthisiology* is attested by numerous reports. In pulmonary tuberculosis, variations in sedimentation rate reflect the intensity of the morbid process more accurately than the pulse, temperature, weight, sputum, symptoms or physical signs. At the Trudeau Sanatorium<sup>5</sup> it was found that in some instances an increase in rate gave warning of relapses even before new shadows were found in the roentgenogram. No better claim for the test than this can be made, for the value of the roentgenogram as an index of the condition of the tuberculous patient is well established. When one considers the expensiveness of roentgenography and the difficulties sometimes encountered in interpretation, as compared with the simplicity of the sedimentation test, the importance of the latter becomes apparent. It does not, of course, offer any evidence regarding the extensiveness of the tuberculous lesion. The sedimentation reaction indicates the intensity and activity of the inflammatory process. In extensive and yet quiescent fibrotic lesions, sedimentation is less than in limited tuberculous processes with marked tissue disintegration.

The sedimentation test is favored by some investigators even in comparison with the various leukocytic indices. The value of the latter depends in large measure on the ability and interest of the observer. Differential leukocyte counts performed in a cursory manner by persons with inadequate train-

ing are of little value. Here again the simplicity of the sedimentation test gives it an important advantage.

In patients who are not under constant observation, the sedimentation test is especially valuable when repeated at regular intervals. Again, it is important in those receiving pneumothorax therapy for here collapse of the lung makes physical signs and roentgenograms of less value than usual.

A few observers have reported the finding of normal sedimentation rates in the presence of active tuberculous infection. Most workers will agree, however, that such a finding is extremely rare and usually represents a technical error. At the same time it must be pointed out that in severely cachectic stages of tuberculosis, the sedimentation rate has occasionally been found to be normal, or at least slower than earlier in the disease.

In the study of *rheumatic fever*, the sedimentation test is gaining an important place. Its value is found particularly in rheumatic carditis, where it is regularly accelerated. Except when associated with congestive heart failure, a decreasing rate nearly always reflects diminishing activity of the rheumatic process and as an index of this the sedimentation reaction is much more valuable than the temperature, pulse rate or leukocyte count. It has been found that an increasing rate presages clinical exacerbation and many clinicians now permit no activity on the part of the patient until the sedimentation rate has returned to normal.

In *acute cardiac infarction* and in syphilitic aortitis the sedimentation rate is accelerated, whereas in angina pectoris and hypertensive heart disease the rate is normal. In cases of cardiac infarction the test is a valuable guide in deciding upon the duration of rest because in this condition, as in rheumatic carditis, an accelerated rate may be the only evidence of activity of the morbid process.

Rheumatoid, tuberculous and gonorrheal arthritis, and other inflammatory *diseases of bones and joints* are associated with accelerated sedimentation rates, whereas in hypertrophic or osteo-arthritis, the rate is usually normal. For this reason, the test has been used in aiding the differentiation of rheumatoid from osteo-arthritis. In this respect, however, it has not always been found reliable.

In *gynecologic practice*, the sedimentation test has achieved a position of great usefulness. The principles involving its use are the same as those already outlined. Uncomplicated benign tumors, such as fibromyomata or ovarian cysts, mild infections or quiescent inflammatory disease, are associated with no increase in sedimentation rate, whereas when there is active inflammatory disease the rate is accelerated. Degeneration of benign tumors, twisting of the pedicle of an ovarian cyst, and often malignant disease, are associated with rapid rates.

Since the sedimentation rate is not usually increased in pregnancy until the tenth or twelfth week, the test can be used as an aid in differential diagnosis and as an indication of the presence of complications in cases of abortion and ectopic pregnancy. Retention of uninfected products of conception, hemorrhage or infection causes acceleration of various degrees.

In acute and subacute salpingitis the rate is greatly increased whereas in acute appendicitis only slight increases usually occur. Subsidence of pelvic infection is associated with return of sedimentation rate toward normal. Many gynecologists have found this fact a useful guide in indicating a favorable time for elective operations.

In aiding the study of *gastro-intestinal disorders*, the sedimentation test has not as yet attained the general application that it enjoys in the fields already discussed. It has been used by some clinicians, however, to facilitate the differentiation of functional from organic disturbances, benign ulceration from malignant, simple diarrhea from enteritis and colitis. The usefulness of the test in these respects is limited. As has already been pointed out, an increased sedimentation rate is not always associated with malignancy and whether or not the rate is accelerated in inflammatory disorders depends on the severity of the inflammatory process. It is of interest to note that in parenchymatous diseases of the liver, sedimentation rate may be actually less than normal. This has been explained as the result of failure to form fibrinogen which, as already mentioned, is closely related to the sedimentation reaction.

Undoubtedly one of the most important uses of the sedimentation test is in *calling attention to the presence of more or less occult diseases*. As a routine procedure to be performed

as part of the general examination of a patient, the test is very valuable, for an accelerated rate may not infrequently be the sole evidence of the presence of disease and serves in this way as an indication of the necessity for further study of the patient.

When the sedimentation test is carried out in the manner here described and the other steps in the use of the hematocrit performed, one obtains, as the result of a minimal expenditure of time and effort, information regarding not only sedimentation rate but also concerning the presence or not of anemia, leukocytosis and icterus.

When the sedimentation test is used as a routine procedure in the examination of a patient, it must not be assumed that a normal rate necessarily signifies the absence of disease. Occasionally it is found, although it is very rare, that the rate is normal in spite of the presence of organic disease. Thus among 444 cases at the Diagnostic Clinic of the Johns Hopkins Hospital in which the corrected sedimentation rate was 10 mm. or less, manifest organic disease was found in 8 instances. In one case of continued fever of undetermined origin the sedimentation was 0 at the end of one hour. In two cases of chronic nephritis with marked renal insufficiency the rate was 0 and 1 mm., respectively, while in a patient who had active pulmonary tuberculosis as well as hay fever, it was 7 mm. Again, in a patient convalescing from amebiasis who still had some elevation of temperature, the rate was 8 mm.

Three of these 8 cases illustrated the importance of recording the uncorrected as well as the corrected sedimentation rate. One patient had acute pyelitis with hydronephrosis, another had carcinoma of the descending colon and the third had cystitis, pyelitis and renal insufficiency. The corrected rates were practically normal (8, 9 and 10 mm., respectively), whereas the uncorrected values were markedly accelerated (37, 30 and 39 mm., respectively). In these instances the accelerated rates were masked by the correction for anemia.

A study at the Henry Phipps Institute in Philadelphia<sup>2</sup> stresses the importance of paying due regard to sedimentation rates which are found to be accelerated although the general examination of the patient is negative. In 177 of 328 individuals who, after routine examination, had been considered

healthy or suffering from only trivial ailments, the sedimentation rate was increased. Reexamination of these patients revealed basal nontuberculous infiltration of the lungs in 96, "latent" apical tuberculosis in 32, positive Wassermann reactions in 35, pelvic inflammatory disease in 5, and possible carcinoma of the lung in 1. Only in 8 cases was there no abnormality found on reexamination.

Criticism of the sedimentation test arises from a failure to understand the nature of the reaction and, as with all laboratory procedures, from failure to appreciate the importance of attention to what may appear to be trivial technical details. It must be emphasized that slight alterations from the standard technic may cause great differences in results. As has been pointed out, "correction" for anemia may occasionally be misleading. While correction should be made, the uncorrected rate and the hematocrit reading should be recorded as well as the corrected sedimentation rate. Again, it may be repeated that normal sedimentation velocity may occasionally be found in the presence of disease. Finally, it must be stressed that the reaction is a nonspecific one referable to no particular disease and only indirectly of value in differential diagnosis.

## CLINIC OF DR. THOMAS A. C. RENNIE

HENRY PHIPPS PSYCHIATRIC CLINIC, THE JOHNS HOPKINS  
HOSPITAL

---

### RECOGNITION AND MANAGEMENT OF THE NEUROTIC PATIENT

WHEN do we consider the complaint of a patient a "nervous" one? What facts give us the right to speak of a neurosis? Most physicians recognize a vast group of individuals who complain regularly and monotonously and about whom they are never able to find sufficient physical findings to account for the multiple complaints. We might, therefore, speak of the neurosis as a complaint disorder, and by conservative estimate, 40 per cent of any general practice is made up of such complainers. The "neurosis" or "psycho-neurosis" is a misnomer implying, from the days of Weir-Mitchell and rest-cure therapy, a fundamental weakness of the neuron system. Today we know that the neuron is unimpaired, and that these conditions represent personality difficulties often predicated upon inability of the individual to stand the stresses and strains of his life; in brief, one who has failed in achieving essential satisfaction out of life.

These are individuals who come to the office regularly or make the rounds of doctors, each time reiterating their multiple discomforts, often presenting at each visit new and variable ones. Some of these are clearly "mental," such as compulsions for handwashing; phobias and fears of germs, dirt, homicidal possibilities, etc., recognized by the person as "mental" and thoroughly illogical, but against which he has no defense. More often, the patient feels no responsibility for his symptoms, and complains of general nervousness, tearfulness, trembling, "jitters," tremors, or hypochondriacal insistence on aches and pains, multiple and diffuse, affecting any or

all organs. A typical hypochondriac, with his marked over-awareness of bodily functions and sensations, produces symptoms for each system review of the doctor's history, or incriminates a special organ such as head, heart, stomach; expressed as inordinate suffering, multiple and shifting areas of discomfort, and dire evidence of cancer, ulcer, heart disease. Or the neurasthenic is chronically fatigued, working out his disappointments in exhaustion, irritability and insomnia, which keeps him in bed, unable to face the tasks of daily life. The hysteric dramatically simulates standard diseases with numbness, anesthetics, palsies, blindness, aphonia; manifested in pseudoneurological ways and atypical sensory disturbances. A third group, complaining of anxiety symptoms in palpitations, sweating, globus, sense of suffocation and fear of death; tension in dizziness and head sensations, nausea, vomiting, diarrhea, constipation; or motor neuroses as tics of face and head, jerks, spasms, occupational (writer's, telegrapher's) cramps, are usually convinced they have a real disease but may spontaneously recognize the rôle of anxiety, worry, disappointment, and anticipation in exacerbating their symptoms. Occasionally, a patient spontaneously recognizes the true nature of his symptoms, thus speaking of "nervous" stomach, heart, headache, "nervous" exhaustion, vomiting, or diarrhea, "emotional" fatigue, worry and insomnia, etc.

When any such patient does directly or inadvertently mention nervousness, worry, discouragement, apprehension, or "nervous breakdown," he is all too quickly labeled "neurotic," given bromide, and often summarily dismissed as hopeless or, at best, hardly worthy of a busy practitioner's time. Or he is presented with vague terms, meaningless to him, and runs the risk of further complicating his problems with ill-digested terminology, or a note of pessimism. He may even meet brusque dismissal with a statement that his imagination alone is at fault. Such is not true. His various symptoms are painfully real to him, his distress not alleviated by advice to forget himself, which he is equally unable to do.

The physician himself is apt to be equally puzzled. Concepts such as irritable heart, effort syndrome, neurocirculatory asthenia add little to his understanding. He may hide behind suspicion of malingering or subterfuge. Actually he is dealing

with a special type of personality reacting to life experiences as precipitating factors. Tradition blames overwork, desire to attract attention or arouse sympathy, to "escape" responsibility. We need to know that functional changes in essentially normal organs can bring about discomforts and disturbing sensations under states of worry, anxiety, fear. Or protracted states of tension, irritability, and anxiety may mound into states or *attacks* of acute visceral upheaval with tachycardia, choking, sweating, dizziness, and conviction of imminent death. Frustraneous overstimulation, especially sexual and emotional, without adequate periods of satisfaction and relaxation may contribute. Life problems, such as limited finances, work maladjustment, infidelity, worry over religion, family, pregnancy, contraceptive issues, may create states of insecurity which set off overactivity or irregularity in essentially normal organs. Disappointment and traditional sex lore fears, masturbation worries and coitus interruptus may give rise to complaints of profound exhaustion, poor concentration, backache, etc. Or, as in hysteria and obsessions, we may deal with past experiences, *forgotten* ("repressed"), *dissociated* (cut off), and *converted* into fits, pseudoneurological palsies or obsessive doubts, rituals, fears. Freudian psychoanalysis puts the interpretation on mechanisms, repression of unacceptable urges or fancies, particularly related to childhood and infantile sexuality, the "Oedipus" and "inferiority" complexes, etc. We do best to remember that unhappy experiences and memories, anticipations, life and situational strains all conspire to render certain temperaments disabled or neurotic. It is necessary to remember that we deal with a special type of personality make-up in whom "body protests" represent the unbearable strain of life situations.

Any of these conditions may develop accompanying or reactive states of discouragement or depression, and sometimes represent precursors to more serious and sweeping mental disturbances, such as schizophrenic developments and depressive psychoses. Not infrequently, the discomforts lead the individual to seek relief in drinking. Such individuals, being dependent types, may become alcoholics or drug addicts, sometimes as a result of the physician's unwise use of sedatives, hypnotics, and tonics.

**What Is the Neurotic Type?**—The neurotic constitution is difficult to define with exactitude. Difficulties beginning in infancy are frequent. One finds evidence of early instability in the so-called “neurotic” or “neuropathic” traits, namely, excessive timidity, shyness, submissiveness, fears, nightmares, explosive temper, enuresis, nail biting, vasomotor instability, protein sensitivity, allergy, hives, eczema, asthma. These conditions may exist in any social and intellectual level: both in precocious intellectual types and in retarded, feeble-minded individuals; or they may arise during adolescence, which is the decisive period in the formation of the adult personality, particularly with the development of emotional instability, over-conscientiousness, rigid ethical and moral standards, tendencies to anticipate troubles, “to cross bridges before coming to them”; and with hypersensitiveness and aloofness, feelings of inadequacy, and a sense of the individual’s isolation from his group. Or there may be precocious or diminished or abnormal sexuality with its tendency to increasing secretiveness, and satisfaction of cravings in imagination. Thus we find adults who in spite of apparent outward calm are characteristically shy, timid, hesitating, indecisive, easily led, tending to dwell and elaborate on past experiences, anticipating with dread the changes of the future.

This temperament is one poorly equipped to meet the issues of life. Thus we find them responding in any of the above varieties of ways when life situations become troublesome or insistent. Almost any person will react with symptoms if inordinate burdens are placed on him. The neurotic reacts sooner and to lesser burdens. He is poorly equipped, physically and temperamentally, to meet the complexities of adult life.

In physical make-up, too, they are apt to be loosely organized. We find them often as underweight, asthenic types, with visceroptosis, spastic constipation or colitis, requiring more sleep and rest than the average. We find excitable reflexes, unstable autonomic types, with labile pulse and hyperactive sympathetic nervous systems; easy blushing, dermatographia, circulatory and vasomotor instability; hypersensitive skin; menstrual dysfunctions; carbohydrate and water imbalance.

Such physical constitutions react violently to emotional upsets. Many of the neurotic symptoms represent essentially, then, the body protests of the personality faced with insecurity and inability to find satisfaction.

**Explanation of the Neurotic Conditions.**—What commonly lies back of such conditions? The answer is to be found only in an understanding of the personality and constitution and a complete record of the life events. Every personality is different and individual, and consists of its physiologic or biologic component, its particular emotional make-up, its intellectual assets and liabilities, and its special temperamental type. Some of these are inherent in the stock of the person, some are molded and determined by the life events from the moment of birth on. What we are results from the interplay of life experiences and happenings on the original constitutional stuff of which we are made. Every individual functions with certain drives and instincts, his particular quality of intelligence, his sexual rhythm and urges, his social and occupational needs and satisfactions, his religion, family and marital strivings, and all within a certain range made up of a sensible balance between work, play, rest and relaxation. In certain temperaments, any of these components may be subjected to strains impossible to endure with comfort. When that happens, we can get neurotic symptoms.

The exact stuff of the personality is fairly easy to evaluate by any physician sensitive to life problems, willing to listen for forty-five minutes to an account of the patient's life, and able to remain objective and free of personal embarrassment. A simple review with any patient will bring to a focus telling and dynamic facts. The early childhood, with or without its neurotic traits, gives an immediate picture of the essential constitution. The school record gives a clue as to the intellectual status: frequent school failures, or inability to get beyond eighth grade, are apt to be indicative of limited intellectual endowment. It is well to remember that the average adult has an intellectual capacity of approximately eighth-grade caliber. An intelligence test, if it is available, clinches this aspect of the personality. The record of success or failures in jobs gives a clue to the innate dependability and stability of the person and a clue to occupational strains. Every intelligence and tem-

perament has its level at which it works contentedly, beyond which it becomes uncomfortable. An account of the marital and sexual status may bring to light immediate topics of worry or concern, fear of pregnancies, sexual dissatisfaction or distaste, incompatibility between partners, masturbation worries, etc. The financial status and strains are easily evaluated. The degree of success or failure in making friends or the relationship to the family and broader community interests quickly brings out essential problems or lines of sensitiveness. An account of the parents, siblings, and relatives brings out liabilities in the stock.

**What Precipitating Factors Can Be at Fault?**—Any or all of these factors may be the important determinant of the particular psychoneurotic reaction. During such a review, precipitating factors will begin to assume their real importance, especially if their presence correlates in time with the development of the complaints. Such factors are often acute: operations, death in the family, accident, quarrels, fright, chance remark of physician, awareness of anxiety on the part of the physician; more often insidious and prolonged factors lead to a development of strain, tension, anxiety or worry which culminates in the patient's complaint. Irregularity of work, inadequate income, work under pressure, ambition beyond capacity, promotion and the fear of not making good, illness of relatives, religious conflicts, sex ruminations and conflicts, fear of death, conflicting medical statements or advice, and innumerable other life factors take their toll in undermining the patient's confidence and security, leaving him worried, apprehensive, discouraged and puzzled. Any of these states of mind may cause or enhance physical complaints and visceral participation. These are common facts which underlie most psychoneurotic reactions.

**How the Life Facts Work.**—Out of these life problems are produced the neurotic symptoms. Cannon has shown us the interrelation between fear and other emotions, and certain physiologic concomitants that go hand-in-hand. An emotional state is, after all, a physiologic state bringing automatically with it disturbing variations in any or all of our physiologic functions. Thus fear is a condition characterized as much by tachycardia, sweating, dilated pupils, interrupted

gastro-intestinal motility and secretion, adrenalin hypersecretion, and sweeping metabolic changes in metabolism, water balance, etc., as by a subjective awareness of insecurity or danger. In the same way, any emotion, whether it be worry, anxiety, strain, discouragement, or anticipation, carries with it its pattern of concomitant physiologic changes. In years gone by, under the influence of Descartes and Wundt, we spoke of the body-mind relationship or parallelism. Today, we say a human personality is made up of all these factors: a ceaseless interplay and flux between somatic and more specifically "mental" functioning.

**Obtaining the Human Facts.**—Personality and life facts are easy to obtain by any physician who can establish an attitude of confidence, understanding and willingness to deal with everyday human events. Formal history is not necessary. The following questions should prove helpful in eliciting essential components: what is your complaint? When and how did it develop? Were you worried at the time? What things concern or distress you? Were things going smoothly at home, at work, or with relatives or friends? Any quarrels, disappointments, shocks, or fright? What do you think causes your condition? Have you heard things about your illness that worry you? Any relatives or friends have a similar condition? Are you apprehensive about your future, or troubled by memories or past experiences?

Then one goes quickly through the items of a personal review: anything unusual in your childhood? How far did you go in school? Any failures? What jobs have you had? Are you happy in your present work, or are there difficulties? Are you happy in your marriage? How do you get along with husband or wife? Do the children worry you? Any difficulties with the sex part of your marriage? Do you want more children? Do anything to prevent pregnancy? If so, does it worry you? What methods? Any fear of pregnancy? Do sex relations lead to relaxation or unrest? Any worries about masturbation? Any financial problems? Does your religion give you concern? Describe your temperament. Are you moody, cheerful, friendly? Have you any hobbies? Do you enjoy movies, friends, athletics? Any tendency to nervousness in your family?

These human facts serve as the important material for the treatment of the neuroses.

**Treatment of the Neuroses.**—In discussing treatment, one must remember that it must be adjusted to the person and the condition. There are physicians who insist on a diagnosis and work from that basis. There are others who know how to listen and can create an atmosphere of trust. Some work essentially through talking; others think first of general hygiene and finding a level of comfort for their patients. Certain fundamental rules apply to all cases. Only if we accept the inter-related integration of "mental" and physical functioning are we in a position to help the psychoneurotic patient. There is no panacea. Many theories have been advanced for the understanding and therapy of such conditions. Older psychiatry concerned itself largely with the constitution and concept of inherent degeneracy. Later psychiatry emphasized malnutrition, chronic infection and metabolic disturbances, which latter even today has its exponent in the endocrinologically minded physician. Rest, eradication of foci of infection, colonic irrigation, dietary fads, gymnastics, and drugs have all had their day. Pharmacology has recently given us benzedrine as a specific type of stimulant. Psychoanalysis is time-consuming and cures by "talking out" the unconscious repressed memories and phantasies. Today we take from all this whatever seems to promise returns, but prefer a pluralistic working concept which never loses sight of the fact that a person has a life history and life story and that in the biography of the person, one finds facts whose bearing on these conditions cannot be ignored. Treatment, therefore, must be carried out with an open mind and willingness to utilize all avenues of approach.

Treatment begins with the first interview. The complaint has been obtained and its development, and the setting of the complaint has been clarified in an accurate chronologic account of the life situations at the time of onset. We have taken a little time to learn something of the patient's fundamental biologic make-up, his ability to stand strain, his intelligence and its limitations, and his special temperamental liabilities. This may be the first time the patient has had a chance to understand what really is happening inside him. Frequently

the mere chronologic accumulation of symptoms with life events brings with it the patient's own spontaneous realization of the way in which worries cause physical symptoms. This is what we mean by *insight*. The first step is to begin by *settling* for the patient the issue of the suspected organ, acquainting him with the results of examinations and convincing him that he is physically sound. Such an examination should be completed as soon as possible, in order not to undermine the patient's confidence by an impression of uncertainty on the physician's part. Unnecessary or purely investigative procedures may stir up doubts. It sometimes takes rather dramatic conversation and a show of authoritativeness to convince a patient. It is then *explained* to him that the findings are definite and that he has no organic disease; that these symptoms represent the participation of his body in the various emotional states which he has enumerated, and he is shown how the factors which have just been elicited play their rôle in producing the part-participation of the physiologic system. His cooperation must be enlisted in fighting the underlying emotional states. It is often gratifying to see how patients have been groping toward such an explanation in a spontaneous fashion. It is common to hear, "Why, I've known that all along. I knew it was just worry." Others are ashamed to admit that their personalities could get such a rise out of them. Sometimes, the patient must be *persuaded* to accept the real nature of his complaints. It is well, whenever possible, to interview a responsible member of the family, in the patient's presence, and give him the same understanding of the true causes and elicit his cooperation in management.

If the physician takes time to put over these concepts, it is surprising how quickly palpitations, weakness, etc., cease to spell for his patient mysterious and ominous warnings of disease or disaster. In fact, the symptoms achieve a certain respectable status, something tangible and common to most human nature, even the most normal varieties. We urge the patient to accept himself and his make-up as they are. To accept is to shoulder the burden of treatment for himself. Often a single such interview will bring about a real amelioration. When the patient returns, as he usually does, the physician has an opportunity to repeat the same explanation,

to offer another dose of reassurance and encouragement, and to give him a chance to ventilate new or additional old worries that have a bearing on the condition. Patients want to know how long treatment is likely to take. It is well to give no statement of *time*, as the human tendency is to check off the days in anticipation of the hour of cure. It is better to state frankly that one does not know, that the illness took time in developing, and that the reestablishment of self-confidence involves patience and time. To commit oneself to a time limit is to run the danger of losing the patient's confidence when the time limit has expired and the symptoms have not vanished.

Having achieved this much in the initial interview, we may then set out to meet the environmental and precipitating situation. When the patient is willing, we can accomplish a great deal in *reorganization* of his life. Where intelligence is low, and a job or school constitutes an unbearable strain, we recommend change, and even attempt to arrange such with the employer. In the same way, we may have to count on the cooperation of schools, and of relatives and friends. As a rule, we urge such patients to return to work, to *accept* the true nature of their complaints, to put up for the time being as well as they can with their distressing symptoms and to get back into the rush of life, or to return and face the troublesome situations. It is imperative to avoid medical terms, however vague, as they seldom connote to the patient what they do to the physician. Often it is impossible to modify situations such as limited finances, the care and burden of relatives. If this is impossible, we persuade the patient to *accept* the facts as they are, or to modify his attitude of conscientiousness or resentment toward them so that they become more acceptable.

Usually no one factor is at fault, but the condition represents a variety of difficulties, all of which may need modification. It may be necessary to *desensitize* the individual to his past experiences, giving him some concept of the prevalence of such events in human life. It may be necessary to give contraceptive advice or hygiene of normal sexuality, which takes the shame and fear away from masturbation, which teaches the wisdom of avoiding unnecessary sexual stimulation in fact or in fancy. The entire aim is to reestablish the patient's confidence in himself and in his physician, to discuss

his problems, however simple and trivial they may appear, in order to bring the relief which objectivating them often accomplishes.

Treatment of hysterical and obsessive conditions is more difficult. Strong positive suggestion of cure sometimes removes the hysterical symptom. Obsessive habits of thinking or behaving have to be deliberately broken up like adhesions, which is only possible with the patient's cooperation and sometimes only in the controlled environment of a hospital. Reassurance about phobias is important. Such patients rarely, if ever, carry out the suicidal or homicidal urges which they so fear. Lasting cure comes only with thorough analysis of the underlying dynamics, which brings the patient awareness of the essentially disturbing factors.

Treatment is not mere talking and listening. Every human being is entitled to some share of satisfactions. It may become necessary to *plan* his life for him to insure his getting maximum satisfaction. It is wise to give him a written schedule which provides for work and sleep, a sensible dietary program, rest, relaxation and play. Substitution of any hobby for idleness and self-preoccupation can be a real boon, just as deliberately giving up daydreaming may avoid unhealthy arousals. Many such a patient has found in gardening, in reading, in regular vacations, in study, in club or church life, or in athletics a real balance for a temperament which tends to be too self-centered. In addition, such a program helps to break up the actual preoccupation with sensations or problems. Any pain becomes worse the longer we think about it. We urge patients to deliberately put aside thoughts about their problems, and to find relief from them in activity.

Attention to the *physical condition* is important. Diet and insulin are effective in increasing weight. Constipation must be combated, preferably by diet, massage and exercise. Enemata should be discouraged; strong cathartics avoided.

The physician has no more useful armamentarium at his disposal for the production of physical relaxation than well-planned *hydrotherapy* and *exercise*. Prolonged soaking of an hour in a tub of water at  $99\frac{1}{2}^{\circ}$  F., or slightly over body temperature, at bedtime or twice a day, often means a real night's sleep and a letting down of the tension of the day. It is well

to avoid any medication, particularly sedatives. No amount of reassurance about the physical well-being can undo the undermining of the physician's words that a prescription can mean. One must strive for consistency. To pronounce an organ sound and then prescribe additional rest or modified activities, or a special diet, is to leave the patient with a serious doubt as to the original pronouncement. In spite of all advice, the general physician will probably resort to some sedatives because it seems his only way to hold his patient through a difficult time. If sedative is used, it should be accompanied by careful explanation that the medication is only a means of producing symptomatic and temporary relief; that it is an artificial means of easing painful symptoms or anxieties in order that he may ultimately correct the more fundamental attitudes, situations, or concepts leading to the insecurity with regard to himself. Barbitol, luminal, sedormid, dial and amytal are simple to prescribe, and effective. Sympathetic nervous system depressants and antispasmodics often bring real relief. Tincture of belladonna may relieve spastic gastrointestinal states. Ergotamine tartrate or gynergen in 1-mg. doses two or three times a day may be helpful in toning down too active a sympathetic nervous system.

It is rare that a psychoneurosis develops after thirty without there having been precursors of the reaction during previous life periods. The physician likely to succeed is the one humanly interested in his patient's story. The patient senses an attitude of understanding which no physician can feign. Any state of general nervousness, tension, anxiety, hypochondriasis, or neurasthenia can be adequately and successfully treated by the nonspecialist. Patience is necessary as well as the ability to sustain interest. One must not fail with reassurance and encouragement or become bored with the slowness of response. One must become sensitive to the events of his patient's lives, and learn to interpret and deal with them. In this, the old time practitioner was an intuitive artist, but without intuition and without art, one can acquire medical and human wisdom without sacrificing one's status as objective scientist.

## CLINIC OF DR. LESLIE N. GAY

### THE JOHNS HOPKINS MEDICAL SCHOOL

---

#### A CLINIC TO EMPHASIZE THE CLOSE INTERDEPENDENCE BETWEEN INTERNAL MEDICINE AND ALLERGIC MANIFESTATIONS

IN his office today the diagnostician finds many clinical problems which are related to allergic manifestations. This has always been so; but during the past two decades our more definite knowledge of allergy has increased our ability to diagnose and treat these special problems. Allergy has become a term well known to the average intelligent layman probably because of the numerous popular articles which have appeared in the monthly periodicals, and for this reason opportunity to diagnose these diseases has increased. But the enthusiasm which greets a new phase in medicine sometimes swings the pendulum so far that judgment becomes faulty and for this reason a note of warning is sometimes necessary to remind us that *the obvious must not be overlooked* while we are searching for an explanation of our problem in the more obscure special fields of diagnosis. And so it happens that a clinic designed to point out the necessity of a better understanding of the general problems of medicine by the allergist and of the necessity for a better understanding of the problems of allergy by the internist and general practitioner is opportune at this time.

#### GROUP I

Case I.—J. S., a girl, aged four years, was brought to me first in June, 1933, with a history of eczema which had begun in infancy. From time to time it would spread over the entire body and was particularly irritating at the folds of the skin. Two years after the onset of her eczema, at the age of three years, she developed attacks of coughing with marked shortness of breath and a running nose. These attacks would last for from twenty-four to forty-eight hours, clearing up and recurring at irregular but frequent intervals throughout the year.

The physical examination was entirely negative; whereas the history definitely suggested an allergic eczema, an allergic rhinitis and an allergic bronchial asthma. Using the passive transfer technic of Prausnitz and Küstner<sup>1</sup> because of the age of the child, we found the patient to be markedly sensitive to the house dust with which she came in contact in her own home. All other tests with suspected protein extracts gave no reactions.

Specific treatment consisting of injections of an extract of dust obtained from the child's home was given and a most satisfactory improvement followed. The schedule of these injections was as follows:

## CHART 1

## TREATMENT SCHEDULE: HOUSE DUST

1. Treatment consisted of subcutaneous injections of dilutions of a specific house dust extract. The material was prepared by adding Coca's extracting fluid<sup>2</sup> to a given quantity of dust. This fluid was then decanted after three days, passed through a Berkefeld filter, cultured for sterility and diluted for treatment.

2. Treatment was given every three to four days.

Dosage: *Dilution 1:1000*

0.1 to 0.9 cc.  
(6 doses)

June 22 to July 6.

*Dilution 1:100*

0.1 to 0.9 cc.  
(6 doses)

July 6 to July 27.

*Dilution 1:10*

0.1 to 0.9 cc.  
(8 doses)

July 27 to August 30.

3. After 0.9 cc. of 1:10 dilution was reached this amount was given once each week for a period of six months. At the end of this time, the symptoms had entirely subsided and the injections were discontinued.

<sup>1</sup> The Prausnitz-Küstner technic consists of the injection of the serum, taken from an allergic suspect, into the skin of a known nonallergic recipient. This serum locally sensitizes the normal skin and after twenty-four hours specific allergens can be injected locally into the sensitized sites. The union of the allergen with the specific sensitizing reagents will produce a reaction similar to that which one can obtain by testing directly the allergic suspect if he is sensitive to the specific material.

<sup>2</sup> Coca's solution:

2.8 Gm. sodium carbonate.

5 Gm. sodium chloride

4 cc. 95 per cent phenol.

1000 cc. distilled water.

On January 27, 1936, the child's physician again consulted me because, in his opinion, the child had developed definite allergic manifestations referable to the gastro-intestinal tract. For the previous eighteen months while taking the above injections, she had been free from all respiratory symptoms. However, six months before the second consultation it was noted that there was a recurrence of nasal discharge, occasional sneezing and acute abdominal pain which came at any time of the day or night, either after eating or unrelated to food. There was also at times a definite rise in temperature, but on several occasions the temperature had been quite normal although pain was severe. With the last attack of acute abdominal pain, the week before I saw her, she had had a severe attack of asthma.

Physical examination showed a very well-nourished child—a great improvement in comparison with the condition existing on her first examination in 1933. There were no râles in the chest, but there was some mucous discharge from the nose. The abdomen was entirely negative except for slight generalized tenderness over both lower quadrants.

The intradermal food tests performed on the child were negative, but she now showed a definite reaction to *orris root* as well as to *dust*.

Blood morphology showed a slight secondary anemia but with no eosinophilia. Day and night specimens of urine during the period of examination showed scattered clumps of pus cells; catheterized specimens contained many pus cells and bacteria (*Bacillus coli*).

An acute pyelitis, rather than food allergy, was found to explain the gastro-intestinal symptoms in this child and by proper treatment the laborious diet regulation was avoided. The return of asthmatic manifestations, it is true, somewhat masked the picture, but these symptoms diminished when orris root powder was eliminated from her environment.

The patient was treated as one suffering from recurring attacks of pyelitis. Since August, 1936, she has been entirely free from symptoms, the urinary infection having been controlled by the simple measures used in the management of acute pyelitis.

Case II.—B. G., a girl, aged five years, was brought to us first in August, 1936, with a history of urticaria. The eruption was distributed all over the body, but was more annoying on the extremities than on the trunk. Associated with the urticaria there were crises of nausea, vomiting and generalized abdominal pain. There was occasional slight fever, as high as 99.6° F. These episodes had been recurring about once in two months for two years.

Examination showed a well-nourished child. An innocent appendix had been removed a year before she came to us. Her physician felt that she was having definite gastro-intestinal allergic reactions in conjunction with the urticaria. Physical examination was entirely negative. The blood morphology was normal and there was no eosinophilia. All intradermal protein tests were negative. Repeated urine examinations showed scattered pus cells in several catheterized specimens. During the examinations which were carried on rather

slowly because of the age of the child, she suddenly developed an extensive urticaria, a rise in temperature to 99.8° F. and acute generalized abdominal pain. During this episode a careful study of the urine was made and numerous clumps of pus cells were found in repeated catheterized specimens, the cultures showing the presence of *Bacillus coli*.

This case presents a striking example of the relationship between infection and urticaria. In a report by Fink and Gay, in 38 per cent of 170 patients who were suffering from urticaria the skin symptoms were found to be due to some obscure infection; and by the removal of the focus complete relief was obtained in 74 per cent. Such cases serve to emphasize the importance of a careful diagnostic survey before a snap diagnosis is made that the appendix is at fault or that some innocuous food is causing the mischief. This was an example, not of food allergy, but rather a reaction of the capillary bed to the absorption of toxic products associated with a chronic low-grade pyelitis.

## GROUP II

The possible association of mechanical factors with allergy must never be overlooked. The presence of a foreign body, as a possible explanation for the acute paroxysms of cough must always be thought of in patients suffering from asthma, especially before the age of twelve years, and the offender must either be localized or excluded. The patients belonging to a group now presented are in the third and sixth decades, however, and their symptoms were not secondary to aspirated foreign bodies; neither were they to be explained on the basis of allergy, in spite of the fact that the histories pointed to that special field.

**Case I.**—M., aged thirty-four years, first consulted us in March, 1933, complaining of violent and frequent sneezing spells during one year. Her sneezing spells had been recurring since February, 1932, without any remission. They had been quite acute, coming on suddenly at any time of the day or in the early morning hours. They were associated with a nasal discharge of watery fluid, free from pus. An episode of sneezing might last for an hour; but between them she would be free from all discomfort.

It is important to note, in the past history, that she had occasionally required treatment of the sinuses. An operation had been performed for an acute ethmoid infection in 1925. In 1926 she had spent eighteen months in Saranac because of tuberculosis of the right lung. It is, also, of importance

to mention the fact that she had had a tuberculous fallopian tube removed in 1930.

Our original examination showed a patient somewhat undernourished with an inactive pulmonary tuberculosis of the apex of the right lung. The blood morphology was entirely negative, except for a mild secondary anemia. There was no eosinophilia. Sputum examination and urine analysis were negative. x-Rays of the lungs confirmed the presence of an old fibroid lesion of the right apex.

Complete study of the allergic factors revealed nothing, except a violent reaction to orris root. As the patient was a nurse, it was quite difficult for her to avoid orris root. Therefore, specific treatment was prescribed. The schedule of treatment was as follows:

### CHART 2 TREATMENT SCHEDULE: ORRIS ROOT

1. Injections of dilutions of orris root extract were given subcutaneously without interruption for one year.

2. Treatment was given every third day.

Dosage: *Dilution 1:1000*

March 10 to March 25.

0.1 to 0.9 cc.

(6 doses)

*Dilution 1:100*

0.1 to 0.9 cc.

March 25 to April 7.

(6 doses)

*Dilution 1:10*

0.1 to 0.9 cc.

April 7 to May 5.

(8 doses)

After May 3, 0.9 cc. of the 1:10 extract was given once each week until April, 1934.

I kept in touch with this patient during the year following my first examination. The allergic rhinitis was relieved, but quite suddenly, in April, 1934, she began to complain of persistent cough and a definite asthmatic tendency. The cough had been frequent for at least a month before the reexamination was made; and every night upon retiring, she had been disturbed by prolonged paroxysms of asthma.

Examination showed numerous râles of a wheezing type throughout both lungs. She had evidence of an asthmatic bronchitis with definite emphysema. The allergic tests were repeated but no additional information was obtained, except a persistent reaction to orris root.

At my second examination a small nodule, measuring about 2 cm. in diameter, could be found in the right lobe of the thyroid gland. It was quite hard, and pressure induced cough. The basal metabolism was normal. It was my impression that this nodule might be larger than the external examination

indicated. I suggested the removal of the gland to eliminate pressure on the trachea. However, my medical associates were rather against this procedure, as the nodule was thought to be inconsequential. But because of the persistence of the cough, loss of weight, and the increased asthmatic discomfort, the patient finally submitted to operation. The right lobe was removed by Dr. William Rienhoff and much to our amazement a large mass, the size of a hen's egg, was found in the lobe projecting back against the trachea. It was quite firm, and on section was found to contain a large quantity of caseous matter. Pathologic sections confirmed our impression formed at the operation that this was a tuberculous thyroid gland. Its removal immediately relieved the cough and the bronchitis, and the asthma attacks ceased.

There has been no recurrence of asthma, excepting occasional wheezing after any acute respiratory infection.

This case is presented as an example of a number of similar patients whose condition might be considered as purely allergic, when as a matter of fact an intercurrent disease may prove to be the sole explanation of the symptoms.

I have on record 5 asthmatic patients sent to us for diagnosis of possible allergic phenomena; in all the simple removal of large adenomatous nodules in the thyroid gland relieved the pressure on the trachea and recurrent laryngeal nerve and at the same time cleared up the asthmatic symptoms.

**Case II.**—The patient, H. W., aged sixty-six years, was referred to me in January, 1937, with a history of recurring attacks of asthma beginning three years before, at the age of sixty-three. The attacks began with definite bronchitis, severe paroxysms of cough, and shortness of breath, both without and with exertion. For a time, he carried on his occupation as an architect without great discomfort. For the last year, however, he had been orthopneic. The attack of coughing had been violent. There had been continuous wheezing and difficulty in both expiration and inspiration. He had raised a rather thick, often foamy sputum, but free from blood. Occasionally, he had been able to control his asthmatic attacks with doses of adrenalin, but on admission to the hospital he had reached the point where any form of medication failed to relieve him.

When the patient was brought to Baltimore, he was in a semiconscious state due to the partial asphyxiation with which he was suffering. He was intensely cyanotic, his breathing was extremely labored, and there seemed to be greater difficulty with inspiration than with expiration. All accessory muscles were brought into play by his breathing. There was marked retraction of all interspaces with each inspiration, particularly on the right side. The veins stood out prominently on the neck throughout expiration as well as inspiration.

Examination showed four remaining snags in the lower jaw. The other teeth had been replaced by plates. There was rather marked emphysema, the costal angle measuring about 160 degrees. The diaphragm was low and excur-

sion was quite limited. Percussion of the lungs was everywhere hyperresonant. The breath sounds were distant, expiration being quite prolonged, and there were numerous sibilant scattered râles over both lungs. The heart showed a slight enlargement to the left and also to the right. There was a definite gallop quality to the sounds. The rate was 110. A soft systolic blow was heard along the left of the sternum. The first sound was reduplicated. There were no diastolic murmurs. The blood pressure was 110/84. There was moderate arteriosclerosis. He was undernourished for his age and height. His temperature was 100° F.

*Special Examinations.*—*x*-Rays of the sinuses were essentially negative. *x*-Rays of the teeth showed abscesses at the four roots. The electrocardiogram showed a normal sinus rhythm. The T waves were all upright. The first lead was normal. There was a sinus tachycardia. The PR interval was 0.16 second. There was, also, considerable depression of the ST interval both in the second and third leads; and it was our impression that the record contributed unquestionable evidence of some disease of the myocardium. The nose and throat examination showed an old infection of the antra and ethmoids, particularly on the right, but no surgical treatment seemed to be advisable.

The most important find in the routine laboratory examinations was the positive Wassermann. Antiluetic treatment was started, and within a week the elevation in temperature, which was found on admission, changed to normal. His cough gradually subsided. The asthmatic tendency diminished, and within eight weeks the patient was entirely free from the attacks. His general physical well-being was remarkably improved and he was discharged from the hospital, to continue his treatment elsewhere. The respiratory distress had all disappeared. The heart was still slightly enlarged, but the quality and rate of the sounds were normal.

I have delayed mentioning the *x*-ray of the chest until completing the presentation of this case. The *x*-ray study revealed an irregular shadow in the posterior mediastinum extending into each lung field, but especially marked on the right. The shadow was interpreted as a large mass of mediastinal glands. The lungs appeared to be clear.

On discharge from the hospital, the patient showed a striking improvement in the *x*-ray findings. The mass of glands had diminished in size, although they were still present. Fluoroscopy of the chest showed no evidence of respiratory embarrassment.

The patient returned for a check of his condition four months after the original study. At this time it was found that the glandular mass had completely disappeared and he was in splendid physical condition. Of course, the antiluetic treatment was being continued, the Wassermann still being positive.

In this case, innumerable protein tests certainly were not indicated. There was no definite basis for a diagnosis of allergic asthma, although this was the assumed diagnosis when he was brought to Baltimore.

These patients, therefore, emphasize the need for careful

consideration of all factors in differential diagnosis before it is assumed that allergy can explain the group of symptoms such as have been presented. In the first instance, the allergic rhinitis was a complication suggesting that the asthmatic attacks were just an added, more severe manifestation of the allergy. The second case, while unusual, should not be confused with any allergic phenomena.

### GROUP III

We shall now discuss a third group which will perhaps exemplify errors that the internist is liable to make if he is not familiar with allergic manifestations. Unfortunately instruction in allergy in our medical schools is still inadequate, probably because of the press of more important subjects, but not a little because the therapeutic results are appreciated only by the trained allergist.

The 2 patients now presented to you afford examples of true allergic hypersensitivity of a most striking type. These children had suffered with their manifestations since infancy. They were the same age and the etiologic factor was one that is frequently encountered and often overlooked by the internist in deciding upon his diagnosis.

Case I.—M. W., aged nine years, gave a history of having had attacks of asthma since the age of one and one-half years. The attacks were perennial in occurrence and were preceded always by coryza and slight soreness of the throat. There was no history of eczema or urticaria. The family history is important from the fact that the father had had eczema. For the three months before she came to us she had been confined to bed with continuous asthma of severe type. She had not been exposed to any unusual amount of powder nor to any domestic pets. Her physician had been unable to relieve her by the usual medication; adrenalin gave only transient relief. For the last three days her attacks had been so severe that she gradually had become cyanotic to such a degree that her physician felt that she might die at the height of an attack of asthma.

When the child was admitted to the hospital she was in a state of acute cardiac decompensation. The condition of the heart improved rapidly, however, under digitalis and much to my surprise two days after her admission to the hospital the asthmatic attacks ceased. Throughout the month's stay in the hospital she was entirely free from them.

The examinations, except for the condition of the heart, were entirely negative. She had an eosinophilia of 8 per cent. x-Rays of the chest and sinuses, eye examination, nose and throat examination revealed no abnormality. The protein tests by the passive transfer technic showed a marked sensitivity

to a number of inhalants, particularly to cotton seed. It was ascertained when the patient came to the hospital that for her entire life she had been sleeping on a cotton mattress. For three months previous to her admission she had been constantly lying on this mattress. Her dramatic improvement was the result of nothing more than the transfer from a cotton to a hair mattress.

Because of the difficulty in entirely avoiding cotton dust, it was thought advisable to give the patient specific treatment with a mixture of cotton seed and house dust. Treatment was started after she was discharged from the hospital and it has been continued up to the present time (two years).

When she entered the hospital the child was extremely undernourished, weighing only 60 pounds. Within a year her weight increased to 89 pounds, and she remained free from all respiratory symptoms. Our scheme of cotton seed dust desensitization has been as follows:

## CHART 3

## TREATMENT SCHEDULE: COTTON SEED LINT

Treatment was given every three to four days.

Dosage: 1:100,000

0.1 to 0.9 cc.  
(6 doses)

June 22 to July 6, 1935.

1:10,000

0.1 to 0.9 cc.  
(6 doses)

July 6 to July 27.

1:1000

0.05 to 0.9 cc.  
(10 doses)

July 27 to Sept. 21.

1:100

0.05 to 0.9 cc.  
(10 doses)

Sept. 21 to Nov. 12 when a constitutional reaction occurred, calling for reduction in dosage.

1:100

0.6 cc. 1:100 extract given every week and not increased, because repeatedly at 0.8 cc. the patient had violent constitutional reactions.

Nov. 12, 1935 to Sept. 1, 1936.

Note: Dilutions were made from concentrated cotton seed extract standardized at 0.7 mg. N per cubic centimeter.

Case II.—H. C. was first seen when he was two years of age in the children's clinic of the Johns Hopkins Hospital in 1926, because of recurring attacks of bronchitis. At that time no special studies were made to determine

whether he was allergic and he was not seen again until May 2, 1934, at the age of nine years. His mother said that since one year of age he had had recurring attacks of bronchitis and asthma. The attacks for at least five years were extremely severe and were thought to be due to an infection in his sinuses. There had at no time been a seasonal variation in the occurrence of the attacks nor had they been related to food nor to environment. They occurred both during the day and night. Between the attacks he had always had what were described as head colds. In 1932 in order to relieve these colds the tonsils were removed, but without any improvement. He had always been exposed to cats and dogs. He had seen a number of physicians before coming to the Johns Hopkins Hospital asthma clinic, and every effort to relieve infection had been made.

Physical examination revealed no serious abnormality. The nose and throat examination suggested an infection of both antra, and x-rays revealed a clouding of these sinuses. It was thought inadvisable to treat them radically because of his age. x-Ray of his lungs showed a moderate accentuation of root shadows. There were no enlarged glands. The heart was quite normal. The protein tests revealed sensitivity of a moderate degree to inhalants, but particularly to kapok. His sensitivity to cotton seed, however, was violent. Less than 0.05 cc. of a cotton seed extract containing 0.007 mg. of nitrogen per cubic centimeter produced a violent constitutional reaction. This reaction was so severe that for a period of two hours constant attention was required to combat the various allergic manifestations that presented themselves. In the sequence of events there was first an immediate laryngeal edema and generalized edema of the mucous membranes of the nose, throat and bronchi. There was violent asthma. To relieve him from these symptoms, it required 3 cc. of adrenalin solution (1:1000), given in divided doses over a period of one hour. After the asthmatic tendency had been controlled and the edema of the throat had subsided the patient developed generalized urticaria. This required an additional cubic centimeter of adrenalin solution (1:1000) in divided doses. The child remained in the hospital for twenty-four hours and seemed very much improved when he was discharged the following day.

An immediate clue was obtained from this violent reaction. The social service investigated the child's home. It was found that he was sleeping on a mattress stuffed with old cotton; much of the cotton was nothing more than floor sweepings or discarded ravelings from a cotton mill. There was a large tear in the mattress and, except for a thin sheet, the ravelings were in close contact with the child's face. Immediately a hair mattress was substituted and for a period of three years this child has reported to the clinic, when requested to do so, with a history of complete relief of the symptoms from which he had suffered since the age of one year. The congestion which had been present in the sinuses has cleared up and there is no evidence at this time of any sinus infection.

It is hardly necessary to call your attention to the fact that inexperience with the problems of allergy was responsible for the years of suffering of these children; in the one instance a fatality was just avoided.

## SUMMARY

These 3 groups are examples of errors in diagnosis made by the allergist on the one hand and the internist on the other. One must admit that a limited specialty is essential in the practice of medicine, whether it be cardiology, gastro-enterology or allergy, but the specialist must not become so warped in his knowledge that his earlier training is completely forgotten. The diagnostician likewise must not limit his knowledge to his basic foundation but should keep abreast of progress in diagnosis and therapy in the specific fields of medical science.

#### THE ARTHRITIS PROBLEM

1. A brief sketch explaining the reasons for the renewed interest in arthritis.
2. The American viewpoint on classification.
3. A discussion of the classification and treatment of arthritis of unknown etiology.

ARTHRITIS is a disease that has existed since the time of prehistoric man. In spite of the fact that it is probably more common than tuberculosis, heart disease, or cancer, it received but scant attention from the medical profession until comparatively recently. This lack of interest can be explained by the fact that arthritis is not a contagious disease, and is seldom fatal. Seventy per cent of the cases are chronic in character, and usually so insidious in onset that even the patient is loath to take his symptoms seriously. Inaccurate classification, lack of exact knowledge of etiology, and the poor results of treatment have long been discouraging factors in all efforts to conquer this disease.

The first serious organized efforts to study arthritis were instigated by some of the leading European governments because of the enormous and continued expense of treating this group of patients among the war veterans. In this country renewed interest in this problem was due largely to pressure exerted by the insurance companies whose main interest lay in shortening the period of disability of the sufferers from this disease.

The pioneer work of stimulating renewed interest on the part of the medical profession in the subject of chronic arthritis in this country was done by Dr. Ralph Pemberton and

Dr. Robert B. Osgood, who did the major work of launching the American Society for the Study and Control of Rheumatism and Arthritis. For the past four years annual meetings have been held in conjunction with those of the American Medical Association. These meetings serve as a center where all available information on arthritis can be discussed and critically evaluated. As a result, the subject has been considerably clarified and to some degree simplified. Although much progress has been made, there are still considerable differences of opinion on the classification, etiology and treatment of chronic arthritis.

For the past three years, the American and English literature on arthritis has been reviewed annually by the reviewing committee of the society. This has entailed an enormous amount of work on the part of the members of the committee. For the year 1935 alone over 600 publications had to be reviewed. Dr. Philip S. Hench and his committee deserve much credit for their untiring efforts to make these reviews comprehensive as well as justly critical. Anyone interested in the subject of arthritis can now be thoroughly informed on the important American and English literature by reading these excellent abstracts as they appear annually in the *Annals of Internal Medicine*. For the year 1936 the review will cover French and German literature as well.

It is now generally recognized that chronic arthritis is perhaps the most important economic problem that chronic disease presents. The previous, almost universal lack of attention to it was due partly to the confusing and discouraging differences of opinion regarding almost every phase of diagnosis and treatment of this malady. It has now been amply demonstrated, however, that in well-organized clinics a large proportion of chronic arthritis cases can be benefited by efficient and systematic treatment. In general from 50 to 75 per cent of the patients can be helped in some degree by proper treatment.

#### CLASSIFICATION

Up to now the complexity of the subject has made it seemingly impossible to arrive at a universally accepted classification of chronic arthritis. This is regrettable because it makes difficult the accurate comparison of the results of treatment

achieved in the various clinics of this country with the results obtained in the European clinics.

The following classification was compiled by the reviewing committee of the American Committee for the Control of Rheumatism and will be utilized to a large extent in the present discussion of this subject:

1. Diseases of joints related to trauma.
2. Diseases of joints due to infection of known type:
  - (a) Gonorrheal arthritis.
  - (b) Tuberculous arthritis.
  - (c) "Tuberculous rheumatism."
  - (d) Pneumococcal arthritis.
  - (e) Scarletinal arthritis; postscarlatinal rheumatism.
  - (f) Syphilitic diseases of joints.
  - (g) Undulant fever.
  - (h) Haverhill fever; erythema arthriticum epidemicum.
  - (i) Septic (purulent) arthritis.
  - (j) Arthritis of subacute bacterial endocarditis.
  - (k) Meningococcic arthritis.
3. Rheumatic fever.
4. Chronic arthritis of unknown etiology:
  - (a) Atrophic arthritis (rheumatoid, proliferative or infectious).
  - (b) Hypertrophic arthritis (osteo, degenerative or senescent).
  - (c) Backache and sciatica.
  - (d) Spondylitis:
    1. Atrophic and hypertrophic types.
    2. The "facet syndrome."
5. Gout and gouty arthritis.
6. Hemophilic arthritis.
7. Psoriatic arthritis.
8. "Allergic," "metabolic," and "endocrine arthritis."
9. Disease of muscles and fibrous tissues.

This classification is the one agreed upon by the reviewing committee; it does not necessarily represent the personal views of all members of the committee or of all the members of the American Society for the Study and Control of Rheumatism and Arthritis. This classification is admittedly not entirely satisfactory to all, but it is the best that has been devised to date.

The confusion in regard to classification is generally in relation to classifying accurately atrophic and hypertrophic arthritis, which, plus the mixture of the two types, comprise about 75 per cent of the cases that the general practitioner is

most likely to be called upon to treat. Because of its practical importance, it is with the group of arthritis of unknown etiology that this paper will primarily concern itself.

Atrophic and hypertrophic forms of chronic arthritis are diseases of unknown etiology. The synonyms most commonly used are rheumatoid for the atrophic form, and osteo-arthritis for the hypertrophic form. The writer prefers these terms for reasons which will be stated later in the paper. In rheumatoid arthritis, which occurs mainly between the ages of ten and thirty years, low-grade infection is presumed to be an important etiologic factor. In osteo-arthritis, occurring predominantly between fifty and eighty years of age, senescent degenerative changes of the joint structures, plus trauma and metabolic disturbances, are said to be important causative agents. While many cases fall into these two groups, it is our experience that the majority of cases do not lend themselves to such clear-cut distinction clinically, and for this group there is the necessity of an intermediate classification. In this paper they will be referred to simply as the mixed type of arthritis.

#### RHEUMATOID ARTHRITIS

**Etiology.**—Eighty per cent of the cases of rheumatoid arthritis occur between the ages of ten and thirty. The patients are usually underweight, flat-chested, and moderately anemic. Foci of infection, active or silent, can frequently be found. Trauma and metabolic disturbances are not important factors in this age group.

The term "rheumatoid" is appropriate because the specific causative organism is not known. The streptococcus is considered to be an important secondary cause. It cannot be regarded as the primary etiologic factor since no one as yet has succeeded in recovering it from the blood stream in a larger proportion of cases than can be found in control groups. Cecil, Nicholls and Stainsby<sup>1</sup> formerly thought that they could recover positive cultures from the blood and joint fluids in more than 60 per cent of their cases, but other workers have not been able to duplicate these results. Davidson and Goldie<sup>2</sup> state: "Our experience in cultivating blood and joint fluids both by the usual methods and by the special technique of the New York workers has been consistently negative."

Agglutination, precipitation, antistreptolysins and sedimentation tests have been utilized recently to emphasize indirect evidence in favor of the streptococcus as a primary etiologic factor. These findings are *indirect* evidence that infection, probably by the streptococcus, is present in the individual: they do not prove that the streptococcus causes the arthritis. Freeman, writing in the Second Annual Report of the British Committee on Chronic Rheumatic Diseases, points out that streptococci are just as adaptable in their immunologic reactions as in their growth characteristics.

Dienes and Bauer,<sup>3</sup> in evaluating these tests, found that the agglutination reaction is of definite aid in investigating the disease but is not practical as a routine test because of the difficulty of technic and the lack of uniformity in the findings. In their opinion the sedimentation rate is the most useful laboratory test for diagnosing cases of rheumatoid arthritis. It was positive in 90 per cent of their patients of that group. However, it was also positive in 50 per cent of the tests in 7 patients with osteo-arthritis and in both of their 2 cases of gout. In the writer's experience, the sedimentation rate was found to be an unreliable diagnostic and prognostic aid. We still employ this test as a routine procedure but find that it often does not agree with the clinical diagnosis or prognosis of the case. We agree with Hench<sup>4</sup> who stresses the fact that, since indirect tests are not yet of practical or of undoubted usefulness, we must continue to rely upon clinical judgment and observation in the management of chronic arthritis.

It seems to the writer that in the future studies of rheumatoid arthritis as well as of osteo-arthritis, our present knowledge will have to be supplemented not only by more specific information regarding the rôle of streptococci in these diseases, but also by a better understanding of the rôle of metabolic factors such as auto-intoxication, disturbances of liver function, and glandular secretion.

**Symptomatology.**—The onset of acute rheumatoid arthritis is very much like that of acute rheumatism. It is often marked by fever and prostration, but differs from rheumatic fever in that it seldom affects the heart and almost invariably causes some permanent damage to the joints. There is multiple joint involvement with pain, swelling and tenderness, and often

effusion into the joints. Chronic rheumatoid arthritis usually has a gradual onset and the inflammation in the joints is less pronounced.

### MIXED TYPE OF ARTHRITIS

In the second age group occurring predominantly between the ages of thirty and fifty, infection is still a prominent factor, but metabolic disturbances, mental and physical strain, and acute or repeated trauma, are increasingly important. A satisfactory inclusive term is needed to describe this group of cases in which the arthritis is so often of the mixed type.

### OSTEO-ARTHRITIS

**Etiology.**—The patients in the third age group suffer chiefly from osteo-arthritis, approximately 75 per cent of osteo-arthritis being seen in this age group. However, even in this age group one sees occasionally a typical case of rheumatoid arthritis.

Some prefer the term "degenerative arthritis"; others, the term "hypertrophic arthritis." The former signifies the degenerative process which is found in these cases in the soft tissues and cartilaginous portions of the joint; the latter is indicative of the hypertrophic bony changes also found at the periphery of the bones. Neither term is entirely satisfactory because of lack of inclusiveness and because of the assumption that infection does not play a rôle in this type of arthritis. Undoubtedly degenerative changes as well as chronic trauma, endogenous or exogenous in character, are important in the development of this type of arthritis. The writer, however, as well as other clinicians, believes that metabolic disturbances and low-grade inflammatory processes may bear a definite causative relationship to this disease. The possibility and the importance of infection in these cases decreases with the advancing age of the patient. Diminished capillary circulation around the joints is thought by some to be of etiologic importance in osteo-arthritis. While this may be true, Nissen<sup>7</sup> has pointed out that roentgen evidence of sclerosed blood vessels is found more often in rheumatoid than in normal controls of that age group. The factor of excessive weight per se, *i. e.*, as a trauma contributing factor, is also probably of minor

importance. These patients are not very much overweight, seldom in excess of 20 pounds.

**Symptomatology.**—Osteo-arthritis is seen ordinarily in fairly robust individuals past middle life. The chief complaints are stiffness and pain in the weight-bearing joints. Ankylosis and deformity are comparatively rare. The onset of the process is gradual and insidious.

It is argued by many that the only effective treatment in these cases is to put the painful joints at rest, to reduce weight, to attempt to increase joint circulation by physiotherapeutic measures, and to tell the patient that there is very little danger of joint ankylosis. We do not wish to belittle these forms of therapy. It is believed, however, that there is at present too great a tendency among clinicians to rely solely on such therapy to the exclusion of an endeavor to regulate the patient's metabolic processes and eliminate factors such as defective liver function, gastro-intestinal auto-intoxication or infection, and other low-grade infections of obscure origin. In our experience the possibility of obtaining a reasonably fair result in osteo-arthritis, if all these methods of treatment are kept in mind and utilized as indicated, is equal to the expectation of a good result in the treatment of rheumatoid arthritis. In spite of adverse criticism, we have insisted for years upon the primary importance of treating metabolic and low-grade infections in addition to the necessity of regulated rest and diet, and the elimination of trauma and postural strain. In 74 cases with osteo-arthritis that have been followed from three to fourteen years, treatment as advocated has produced an excellent result in 31 cases, fair in 15, slightly improved in 10, and has failed in only 18.

#### TUBERCULOUS RHEUMATIC ARTHRITIS

In Europe, particularly in France, a form of arthritis has been recognized in recent years called "tuberculous rheumatic arthritis." It was first described by Poucet in 1897 as a condition somewhat resembling acute rheumatic fever with pyrexia, pain and swelling of the joints, eventually terminating in a tuberculous arthritis of a single joint. Others broadened this concept and advanced the observation that in some cases it resembles atrophic. in others hypertrophic arthritis. The

opinion of the majority is that it represents an atypical tuberculous lesion since tubercle bacilli are not present in the joints. It is looked upon as an allergic manifestation in the joint due to tuberculous toxins from a distant tuberculous focus. In France, 12 out of 16 specialists in arthritis interviewed by Slocumb<sup>6</sup> considered this entity established. In this country, however, very few clinicians recognize this form of arthritis.

#### TREATMENT OF CHRONIC ARTHRITIS

**General Considerations.**—Interest in the treatment of arthritis was intensified in this country by Goldthwait and Billings some thirty years ago. Goldthwait emphasized postural defects and the value of controlled rest and exercise; Billings was the first to point out the necessity of the removal of foci of infection. A few years later Pemberton<sup>7</sup> showed that many of these patients were suffering apparently from a decreased carbohydrate tolerance, and were clinically benefited by reduction of carbohydrate intake. Billings's work stimulated bacteriologists in efforts to find a specific type of streptococcus as the etiologic factor in the disease. The belief became general and is still held by some that vaccines from specific isolated organisms would be as efficient in the treatment of arthritis as, for instance, the diphtheria toxin has been in the treatment of diphtheria.

A few years after Billings's original statement, Miller and Lusk<sup>8</sup> startled the medical profession by reporting a large series of arthritis cases that had been improved by treatment with nonspecific vaccines. Other workers<sup>9</sup> pointed out that the effect of these vaccines was due probably to the foreign proteins contained in the vaccines, and began to utilize other foreign proteins, such as milk and secondary proteins, with equally good results.

After the World War, the value of many forms of physiotherapy such as diathermy, ultraviolet light, baking, massage, and of hydrotherapy was investigated. The cooperation of orthopedic surgeons in the mechanical and surgical correction of joint deformities was sought and utilized. During the past five years efforts have been made to correct vitamin deficiency, or sulfur deficiency, which might be contributing causes in arthritis.

At various times each of the foregoing concepts was stressed, often to the exclusion of all other theories. Very often there was failure to mention in the literature that in addition to the favored remedy other forms of treatment had also been used. Recently, however, it has become the practice to utilize a combined program of treatment, including every recognized form of therapy which may be of value in each individual case. If a patient's economic status permits or if all indicated services and tests are available, they should be utilized. Very often this is not possible and the physician must select those measures which are least expensive and time-consuming, and which at the same time will most likely relieve the patient's symptoms and conserve joint function. It should be obvious that an acute arthritis in a young person demands more energetic measures to safeguard joint function than does an arthritic process in which function has already been seriously damaged. Similarly a patient with low resistance should be given treatments milder in character than would be given to one in robust health.

In the rheumatoid group, in which infection is the outstanding etiologic factor, the most clearly indicated method of attack is the removal of all offending foci of infection as rapidly as the patient's condition permits, the most easily accessible foci being removed first. In the quest for possible foci, all devitalized or crowned teeth should be viewed with suspicion. Devitalized teeth should be x-rayed at least once a year. The tonsils should be inspected for congestion of the anterior pillars and an effort should be made in every instance to force concealed pus from the tonsillar crypts. This is best done by applying pressure with a tongue depressor against the base of the anterior pillar. A latent sinus infection can often be detected by noting whether the patient has a high-pitched, nasal voice, or gives a history of postnasal drip. In every case the antra and frontal sinuses should be transilluminated. If roentgen examination of the sinuses is not available, the patient should be referred routinely to a rhinologist for examination and opinion. Finally, the lungs, gallbladder, gastro-intestinal tract, genito-urinary tract, and skeletal systems should be examined for evidence of infection or toxemia. The patient should be examined for flat feet and faulty posture so that an

effort may be made to eliminate these as contributory factors in the case. With the clinical facts to be obtained by thorough methods of examination, it is usually possible to plan a satisfactory therapeutic régime and to obtain beneficial results in a large proportion of cases of rheumatoid arthritis.

It is important to build up the patient's general resistance by proper diet, adequate elimination and a sufficient amount of rest. Ultraviolet light or infra-red radiation or a combination of both will be found useful for their tonic effect. The acutely inflamed joints must be immobilized for from six to eight days until the active phase of the disease has subsided and then passive and active exercises should be gradually instituted.

While under treatment, analgesics such as sodium salicylate or aspirin are given in maximum doses to relieve pain. For the relief of pain in the acute stage, heat in any form may be utilized, depending upon the facilities at hand: hot wet dressings, hot pads, hot-water bottles, carbon lamps, hot mud packs, or hot poultices. In the chronic stage, baking followed by general massage is probably most efficacious although diathermy and ultrashort wave treatment are preferred by many physicians.

In osteo-arthritis there is rarely bony ankylosis. It is excellent therapy to reassure the patient on this point. Foci of infection are not so important etiologically and for this reason should be removed only when specifically indicated. Old age is not in itself a strict contraindication if it is thought that such removal of a focus may benefit the patient. The patient's weight, if excessive, should be restored to a normal level by a proper dietary régime and medication.

Some cases may show a mild degree of glandular dystrophy. Treatment necessarily depends upon the type of glandular dysfunction present.

It is usually wise to insist on carefully regulated periods of exercise and rest in order to raise the patient's general resistance to the optimum. It is important to increase the elimination of all nitrogenous waste products, particularly uric acid, and for this purpose we give cinchophen routinely. In office practice baking and massage are easily administered. In clinics cabinet baths followed by hydrotherapy are best

utilized. If the joint symptoms are not relieved by these methods, and if roentgen examination reveals that the disability is due in part to mechanical obstructions in the joint, operative removal of bony spurs and "joint mice" is advised. One should be careful, however, in advising operative procedures when the temperature, leukocyte count and sedimentation rates are unduly elevated.

Patients with a mixed type of arthritis are the most difficult to treat. Here one must consider both the removal of all foci of infection and the correction of metabolic disorders caused by errors in diet. Other conditions to be treated are improper bowel elimination, postural strain, trauma, and glandular disturbances.

### METHODS

In the management of chronic arthritis the writer utilizes a combined method of treatment which, as a rule, embraces the following:

- Relief of mental depression.
- Controlled rest and exercise.
- Removal of foci of infection.
- Modification of diet when indicated.
- Drug therapy: aspirin and cinchophen.
- Vaccine therapy.
- Colonic irrigations.
- Physiotherapy and surgery.

In refractory cases the following methods of treatment are also utilized as indicated:

- Gold therapy.
- Sulfur therapy.
- Bee venom.
- Roentgen therapy.
- Vitamin therapy.
- Intravenous bilirubin and bile salts.

**Relief of Mental Depression.**—Insofar as possible, mental strain or depression should be relieved. While it may not be possible to eliminate worries of domestic or financial character, there is one source of worry which should be attacked vigorously, and that is the patient's constant fear that he is

afflicted with an incurable and progressively disabling disease. The patient should be told that there is a 70 per cent chance of obtaining a successful clinical result if he will make an earnest and sustained effort to cooperate faithfully with his clinician. The patient should be warned not to expect any rapid and spectacular results but rather a slow and gradual improvement. Nissen<sup>10</sup> believes that the mental depression is probably part of a poor constitutional background. The writer disagrees with Nissen's viewpoint. He believes, however, that exhaustion of the nervous system contributes to lowering the patient's resistance and thus permits the other etiologic factors of arthritis to gain a foothold. His experience has been that the state of mental depression almost invariably disappears with the progressive improvement of the arthritis. Recently Cobb, Whiting and Bauer<sup>11</sup> reported that they had found mentally upsetting factors at work in a majority of arthritis patients for from six months to several years prior to the appearance of symptoms.

**Controlled Rest and Exercise.**—Adequate or complete bed rest is of primary importance in cases with acutely inflamed joints. After the initial inflammatory stage has passed, however, it is generally not necessary for the patient to remain in bed. The physician should insist, however, upon a rest period of an hour or two during the afternoon. Prolonged bed rest is contraindicated because of the danger of loss of motion from joint adhesions and from possible ankylosis. Exercise in bed *under medical supervision* should be started as early as possible in every case, and continued when the patient is out of bed. In this way the normal range of motion can very frequently be reestablished. The important point to remember is that the patient must have the proper amount of sleep. If exercise is not carried out to the point where it results in pain with loss of sleep one need not fear that exercise will prove harmful to the patient.

**Removal of Foci of Infection.**—It is difficult to understand the reason for the conservative attitude maintained by many clinicians in regard to the removal of foci of infection, as in many cases spectacular results are obtained following such removal, especially in young people. While the beneficial results obtained in older people are not so startling, neverthe-

less, in the majority of cases the results warrant the slight risk involved. While the results of removal of infectious foci are more brilliant in the rheumatoid type of arthritis, sufficient benefit to the patient is also obtained in the osteo-arthritic type to warrant this procedure as part of the combined attack of the clinician in fighting this disease.

(a) *Tonsils* as a rule are the most important source of infection and should always be removed in a patient with a history of repeated attacks of tonsillitis or if pus can be expressed on pressure against the base of the anterior pillar. In suspected cases of tonsillar infection it may be necessary to use suction in order to establish the diagnosis of latent infection. A frequent source of infection is to be found in the remnants of tonsils previously removed either by surgery or by electrocoagulation. Even if the presence of pus cannot be demonstrated in the tonsils at one or two examinations, persistent congestion of the anterior tonsillar pillars is presumptive evidence that a low-grade tonsillar infection is present.

(b) *Teeth* are next in importance as potential foci of infection. It is advisable to obtain a complete roentgen examination of the mouth in every patient. Devitalized, crowned and filled teeth should receive particular attention. All teeth showing apical abscesses should be removed in the early stage of treatment. The decision as to whether a dead tooth should be removed is sometimes difficult to make, and in general should be made after due consideration of the following: if the root canal of a single root tooth is completely filled, there is probably little danger of infection from this source; if incompletely filled, it should either be removed or the root should be properly filled. All devitalized teeth with multiple roots are to be regarded with suspicion, even though they do not show apical abscesses. It is very difficult, as a rule, to fill these root canals on account of their tortuosity. In patients whose teeth have been partially or wholly removed it is wise to examine the jaw roentgenographically to be sure that no infected root fragments are still present.

(c) *Sinuses*.—While acute sinusitis is usually associated with unmistakable pain over the affected sinus or by severe and uncontrollable headache, in many cases the onset is more insidious and the typical severe frontal or occipital headache

or pain over the antra may be absent.<sup>12</sup> In these cases a low-grade infection may exist in the sinuses and be entirely unsuspected by the patient and his physician. This is particularly true in the damp, quickly changeable climate such as is found on the Eastern coast. In rare instances these sinus infections may escape detection by the radiologist, but even these rare cases can be accurately diagnosed by the combined efforts of a competent radiologist and rhinologist.

If the sinus infection is of moderate severity, cases are sometimes handled successfully by the ultraviolet light, diathermy, or ultrashort-wave treatment. Others require one or more series of sinus irrigations to effect an improvement in the condition of the sinuses. In our experience irrigating methods have been relatively successful in the acute cases. In chronic sinusitis where definite chronic inflammatory change of the mucous membrane has taken place, it may be necessary to resort to radical surgery in order to clear up the focus of infection. In a carefully selected group of our cases this procedure has been carried out with very satisfactory and permanent results.<sup>12</sup> In both the acute and intractable cases it may be advisable to send the patient to a warm, dry climate such as in Arizona or New Mexico.

(d) *Remote Foci of Infection.*—Foci of infection occasionally occur in the lungs, gallbladder, gastro-intestinal and genito-urinary tracts and skeletal structures. These foci should be studied as possible etiologic factors. Due to inaccessibility, the risk entailed by their removal is correspondingly great, and it is our custom to defer the removal of such foci as long as possible, in the handling of an intractable case. The writer has not seen a single instance where the removal of a focus of infection permanently aggravated the arthritis. Many physicians object to the removal of such foci on the ground that they have not observed beneficial results following this procedure. It is possible that in such cases the foci of infection were incompletely removed or that other unsuspected foci were overlooked and continued to act as a source of infection. Our experience coincides with that of Pemberton<sup>13</sup> who found, in a careful review of 300 cases in which the focus of infection was supposed to have been entirely removed, that 79 per cent with atrophic and 81 per cent with hypertrophic arthritis still

harbored foci of infection when they came to him for examination. Removal of such unsuspected foci has often proved most helpful in obtaining a satisfactory therapeutic result.

**Diet.**—The earlier workers in the field of arthritis were firmly convinced that an excessive intake of proteins or purins was an important etiologic factor in the production of chronic arthritis. At that time, however, the clinical differentiation between chronic arthritis and gout was not sharply defined. Pemberton first pointed out the etiologic importance of an excessive carbohydrate intake, and as a result a great majority of the cases of chronic arthritis were placed on rigidly restricted diets, sometimes to the detriment of the patient.

Gradually it became apparent that in chronic arthritis we are dealing with two types of individuals: one, the undernourished individual, found mainly in the younger, infectious or rheumatoid group, and the other, the moderately overweight individual, found mainly in the senescent or osteo-arthritic group. In the former, it seemed unwise, due to already lowered resistance, to deplete vitality any further, and physicians began to advise placing these patients on a full diet with adequate vitamins to build them up. Fletcher<sup>14</sup> advanced the theory that a diet low in vitamin B was an important factor in the production of chronic arthritis because this deficiency leads to colonic dilatation, intestinal stasis and poor elimination. The accuracy of this view will be discussed later in connection with other forms of vitamin therapy.

Many patients who are overweight are undoubtedly benefited by restriction in diet, to the point where their weight becomes normal. The rationale for the improvement in these cases is still under discussion. Pemberton feels that a reduced carbohydrate intake produces a reduction of the metabolic load which in some manner, as yet not clearly understood, benefits the joints. With this view the writer is in complete accord. Others believe that carbohydrate restriction in arthritis has no beneficial effect except that it reduces the weight of the patient and so lessens the load on the weight-bearing joints. This argument seems weak because one sees a great number of people in America who are moderately overweight, but only a relatively small proportion of overweight individuals suffer from arthritis.

Langstroth<sup>15</sup> advanced the theory that rheumatoid arthritis may be due to diets that are relatively low in protective foods such as fresh fruits, and are also low in calories. Boots<sup>16</sup> believes that a low carbohydrate, low protein diet does more harm than good. Pemberton considers the edema of arthritis to be due to a low serum albumin, and for this reason regards protein restriction as harmful. Lockie<sup>17</sup> found that restriction of carbohydrates is of no particular merit and that an excessive intake does no apparent harm. Hench<sup>18</sup> reported that the administration of 400 to 800 Gm. of carbohydrates daily for many weeks did not bring about a recurrence of symptoms in cases of atrophic arthritis where symptoms had been temporarily inactivated by the presence of intercurrent jaundice.

There is no general agreement on the subject of diet. It has been our practice to regulate diet according to what appear to be the requirements of the patient, taking into account his appearance, weight, blood chemistry values, and the probable efficiency of elimination.<sup>19</sup> The basic diet should, as a rule, be as generous as possible and include as much fresh fruit, raw vegetables and milk as is consistent with well-being and the maintenance of normal blood chemistry values. We usually restrict the carbohydrate intake if the blood sugar is above 120 mg. per 100 cc. of blood. We also restrict the intake of proteins and purins if the blood uric acid is above 3.5 mg. per 100 cc. Fats are restricted if there is a history of cholecystitis.

**Drug Therapy.**—The writer depends largely on the use of cinchophen and aspirin in the routine treatment of chronic arthritis, beginning with 7.5 grains cinchophen three or four times a day. If this is not sufficient to control the pain, an additional 5 grains of aspirin four times daily is advised. Cinchophen is never increased beyond this limit because of the possible danger of cinchophen poisoning.<sup>20</sup> Apparently this is a safe dose because for the past fourteen years we have used cinchophen in this manner in the arthritic clinic in the Hospital for Ruptured and Crippled, as well as in private practice, without any serious toxic effects. During the first two weeks of treatment the patient should be seen at least three times a week, and later not less than once a week, as long as cinchophen is being administered. Signs of skin irritation, particularly itching, are looked for. If such irritation occurs, all medica-

tion is immediately stopped until the skin irritation disappears. We have occasionally encountered a slight degree of urticaria which has persisted for one or two days and occasionally as long as a week. Itching and urticaria can usually be promptly controlled by hypodermic injections of 10 minims of adrenalin, repeated every two or three hours if necessary.

Cinchophen is a very important drug for which there is no substitute. It is the only one that controls pain and has a definite chologogic effect. The combination of aspirin and cinchophen in the dosages mentioned seems to be sufficient to control the pain in the great majority of all cases of chronic arthritis. It is unnecessary to use narcotics except in occasional instances. If the pain is not entirely controlled by the dosage prescribed, or if there is evidence of gastric irritation, we have found that we can obtain alleviation of pain by giving relatively large doses of sodium salicylate per rectum. In obstinate cases we not infrequently give as high as 200 to 300 grains of sodium salicylate in this manner. In the cases in which it is necessary to stop all medication because of transient urticaria, cinchophen medication can usually be resumed successfully after the urticaria subsides, by starting with very small doses, or by substituting tolysin for cinchophen.

Many authorities prefer neocinchophen or tolysin to cinchophen, as these are supposed to be less toxic. They are also definitely less efficacious and consequently larger doses of these drugs must be given to obtain satisfactory results.

**Vaccine Therapy.**—In spite of skepticism expressed by some members of the medical profession in regard to this method of treatment, vaccines have a definite therapeutic value in the treatment of chronic arthritis. They probably act by stimulating the reticulo-endothelial system and produce increased leukocytosis.

If large doses are given intramuscularly or smaller doses intravenously, the temperature usually rises from normal to 100° or 102° F., and by increasing the dosage it can be raised gradually up to 107° F.<sup>21</sup> It was originally thought that the increased temperature might be the chief cause of the beneficial effect, the increased heat probably inhibiting the growth or actually killing the bacteria in the blood stream. However, this possibility is a very remote one, because the only

organism that might be susceptible to this temperature would be the gonococcus. The streptococcus which is the organism generally believed to be associated with arthritis is even more resistant to heat, and most workers hesitate to subject their patients to the risk of temperatures higher than 106° F. The chill is another factor which may be responsible for the beneficial results observed following vaccine therapy. During a chill, there occurs a systemic dilatation of the capillaries and increased circulation may have some beneficial effect.

Although the exact explanation of the benefits derived from vaccine therapy to date is not entirely clear, there can be no question that beneficial results are occasionally observed. Conservative workers put the ratio of improvement at 1 in 4 cases, but even this ratio is worth remembering when treating the refractory case.

Originally there was great enthusiasm for autogenous vaccines. Gradually it became evident that stock vaccines produced equally good results. Miller and Lusk reported a large series of cases of acute, subacute, and chronic arthritis successfully treated by the use of typhoid vaccine. Following this report the writer in 1915 attempted to confirm these results, working on the problem during the following three years in the City Hospital of New York. He found that typhoid vaccine was of definite benefit in the treatment of many cases of acute arthritis but that in chronic arthritis the amount of benefit usually varied in inverse proportion to the length of time the patient had been suffering from the disease. Since 1918 the author has continued to use typhoid and streptococcus both in private practice and in the clinic. Unless the patient can be hospitalized it is better to administer the vaccine subcutaneously or intramuscularly.

Most workers now use either a stock streptococcus vaccine or a streptococcus vaccine prepared on the basis of skin sensitization tests or serum agglutination tests. Many use relatively large doses, others prefer to give the vaccine in small doses with the idea of desensitizing the patient rather than with the intention of precipitating "shock," that is, chill and high temperature. The writer has tried various methods during the past twenty years with the exception of vaccines prepared on the basis of skin sensitization tests. He is not convinced

yet of the practical value of autogenous vaccine therapy. It must be admitted, however, that opinion regarding the efficacy of vaccine therapy is purely a personal matter. It is almost impossible to compare the results obtained by different men because no two physicians ever treated the same series of cases and rarely even the same patient under similar circumstances. There is, however, no contraindication to the use of autogenous vaccines other than the seemingly unnecessary expense entailed in their preparation. Short, Dienes and Bauer<sup>22</sup> state that none of the various methods recommended for the selection of strains from which to make specific vaccines has a solid theoretical or experimental foundation.

As a rule, the object of administering vaccines by the intravenous method is to obtain beneficial results rather rapidly. Small doses, however, may be entirely ineffective and large doses may be dangerous or even fatal. The writer, therefore, usually employs medium doses intravenously.

The slower, safer method of intramuscular or subcutaneous injection is more desirable in office and clinic practice. For routine treatment we use stock nonhemolytic streptococcus vaccine beginning with 2 minims administered subcutaneously twice a week. The dose is increased gradually at each injection until a local or general reaction is obtained. The dose is then maintained at this level for two weeks, after which it is increased to the point where a second reaction is obtained. If the stock vaccine thus used does not seem to be beneficial, we may change to Coley's mixed toxins. It should be remembered, however, that while Coley's toxins are apparently somewhat more efficient than stock vaccines they are more apt to give undesirable urticarial reactions. These reactions occur suddenly, may continue for a week and be most annoying both to the patient and the physician. They are best controlled by ephedrine sulfate,  $\frac{3}{4}$  grain by mouth, three times a day.

The writer is unaware of any contraindications to vaccine therapy. For the patient whose resistance is unusually low it is always advisable to start with a very small dose and build up the dosage less rapidly than in the case of the robust patient.

**Colonic Irrigations.**—Colonic irrigations have proved very helpful in the management of individuals who clinically appear to be suffering from intestinal toxemia as indicated by

sallow skin, coated tongue, mental irritability, fatigue, nausea, flatulence, headaches, and constipation. The exact explanation of the good results is not clear, but the improvement would seem to be due largely to the removal of toxic products originating in the colon, rather than to the direct action of colonic irrigation solutions on the bacteria themselves. Hensch pointed out recently the relative rarity of articular disease in known infections of the colon such as severe ulcerative colitis with diarrhea, blood and pus in the stools. Actually, he points out, arthritis complicates bacillary dysentery in only 3 per cent, ulcerative colitis in only 4 per cent, and typhoid fever in 10 per cent of cases. This relative rarity of arthritis in patients with a specific infection of the colon, however, does not eliminate the possibility that toxic products originating in the colon, either from bacterial activity or from improper digestion, may be absorbed through the portal circulation and become a causative factor in chronic arthritis. It is possible, therefore, that the beneficial effects of colonic irrigations are due to the fact that a considerable quantity of the irrigating solution is absorbed through the portal system, thereby diluting toxins in the portal circulation and liver. Large numbers of bacteria as well as accumulation of toxic products are undoubtedly removed mechanically from the intestine by means of colonic irrigations, and we believe that when beneficial results do not follow colonic irrigations, it may be because the colonic irrigations in these cases were not given efficiently. It is not generally appreciated by the laity or by the medical profession that it requires an especially skilful technic on the part of the nurse properly to administer a colonic irrigation which will satisfactorily remove deleterious intestinal products. This type of therapy has unfortunately been exploited by laymen and has fallen into disrepute in some medical circles. In our own experience colonic irrigations have proved to be an invaluable adjunct in the management of chronic arthritis.<sup>21</sup>

**Physiotherapy and Surgery.**—These methods of treatment will not be considered in this article because of their detailed presentation by other contributors to this symposium.

## NEW METHODS OF TREATMENT

**Gold Therapy.**—Gold therapy has been used extensively in France and England for a decade. It is not surprising that the pioneer work in chrysotherapy has been done in France because the French believe that rheumatoid arthritis is very closely associated with tuberculosis. Forestier<sup>24</sup> conceived the idea that since gold therapy was beneficial in tuberculosis, it might also prove to be beneficial in chronic rheumatoid arthritis. He began his investigation in 1928, and recently reported a six-year study of a series of more than 500 cases, in 60 per cent of which satisfactory results were claimed. In his opinion gold therapy is our most valuable therapeutic agent in treating this condition. He is supported by several co-workers in France and by certain prominent English authorities. American workers, however, have pointed out that the percentage of successful results obtained by orthodox methods used here compare favorably with the results of gold therapy abroad. Moreover, it has been felt that our conservative methods are relatively safer because all gold salts are known to be definitely toxic.

In spite of the fact that Forestier's reports have not been received with great enthusiasm in America, we decided to test for ourselves the efficiency of this method. Appreciating, however, that it is a dangerous drug we proceeded to use it with caution.

We started experimenting with this method two years ago with an initial dose of 10 mg. of gold sodium thiosulfate given intravenously, gradually increasing the amount with each injection. The largest dose we have given in any case was 120 mg. A series of 8 injections at weekly intervals is given and then a rest period of one month is allowed. Following this, a second series of 8 injections is carried out. We insist upon a urine examination before each weekly injection for traces of albumin and urobilinogen. If either is present, treatment is discontinued until the albumin and urobilinogen have disappeared.

To date we have given more than 2000 injections of gold sodium thiosulfate intravenously, and have noted only 18 toxic reactions, the majority of which were in the form of a mild skin eruption which persisted for less than a week. However,

one patient developed a troublesome dermatitis that lasted for two months and another developed an edema of the glottis in which it became necessary on the fourth day to do a tracheotomy for relief of the dyspnea. In both instances the initial dose was 10 mg. and the second dose, given four days later, 20 mg., following which the reactions occurred. In each patient the symptoms completely disappeared. There have been no deaths.

In general the results of this form of therapy were satisfactory. Varying degrees of improvement were obtained in patients who were refractory to other forms of therapy. It may be concluded, therefore, that cases which do not respond to the usual forms of treatment, including vaccine therapy, should be given the benefit of a trial with gold salt therapy. Extreme care, however, must be used in administering this drug.

**Sulfur Therapy.**—Many authorities believe that sulfur deficiency is a prominent factor in the production of arthritis and that, to cure the disease, it is necessary to give sulfur in some easily available form. They support this contention by citing the fact that in some cases of arthritis the cystine content of the body as determined from the finger nails is frequently low, and claim that by giving a sufficient amount of sulfur intravenously or intramuscularly the cystine content can be elevated to normal with accompanying clinical improvement.

Rawls, Gruskin and Ressa<sup>25</sup> have reported that of 33 patients with atrophic arthritis treated in this manner 15 were improved; those with the lowest cystine content received the greatest benefit. Wheeldon<sup>26</sup> has reported 892 cases treated with 40 intravenous and 40 intramuscular injections of sulfur; every case was improved subjectively. Muscle spasm improved in 85 of the cases and joint pain was helped in 65 per cent. Woldenberg<sup>27</sup> treated 231 patients with excellent clinical results, the greatest improvement having been noted following the intravenous administration of 30 mg. sulfur daily for ten days. The majority of his patients were free from pain after 3 to 5 injections. He admits, however, that these patients were also given physiotherapy treatments daily.

The writer's experience with this method has been too limited to date for an expression of opinion as to its value. Following large doses intravenously, patients are apt to de-

velop fatigue, headache, anorexia, nausea, vomiting, chills, and fever; in other words, a typical foreign protein reaction. Sulfur dermatitis is not uncommon. This form of therapy needs further investigation.

**Bee Venom.**—This method of treatment has been used extensively from time to time in Europe and to a certain extent here. For centuries beekeepers have insisted that their occupation prevents the development of arthritis, and that if a patient with arthritis took up beekeeping his arthritis would almost invariably disappear. The literature is full of instances in which physicians have become interested in this form of therapy and have tried to determine its exact field of usefulness as well as to develop some practical method of giving the treatment. Bee venom therapy has certain decided disadvantages. In the first place, it is an impractical form of therapy to administer. Secondly, the efficiency of bee venom depends upon its virulence, and, unfortunately, virulence declines and almost entirely disappears during the cold winter months. We have been testing this form of treatment for the past six months at the clinic on arthritis at the Hospital for the Ruptured and Crippled. To date we have noted an undeniable improvement in several cases that had been very resistant to every other form of treatment.

There are many reports in the literature where an accidental bee sting has actually killed a person. Fortunately, however, patients with arthritis seem to be definitely immune to the poisonous effect of bee venom and many of them can eventually tolerate up to 30 or 40 bee stings at one treatment, without undue toxic effect.

The irritated part becomes inflamed and congested, and this congestion persists for many hours, even days. Usually treatment is commenced with the application of one bee sting and is increased as rapidly as the tolerance of the patient will permit. Patients are subjected to bee sting once or twice a week. The joint is first anesthetized by spraying ethyl chloride on the area to be stung by the bee.

An attempt has been made to prepare bee venom artificially and this is now available in the form of Apicosan. This would be an ideal method of administering bee venom but so far the results with it in our clinic have been unsatisfactory.

The rationale of the treatment is not yet understood. Its action may be similar to the action of vaccine or foreign protein. However, many workers believe that there is an intrinsic property in bee venom which makes it more efficient than either vaccine or other foreign protein therapy. There is another possibility; that the beneficial results may be due in part to the resultant increased capillary circulation.

**Roentgen Therapy.**—The writer feels that roentgen therapy deserves greater investigation than it has had so far. Although we have not had extensive experience with this method it has been definitely beneficial in several refractory cases. The experience of Garland<sup>28</sup> with 30 cases of gonococcal arthritis treated by roentgen therapy led him to conclude that it is equal if not superior to fever therapy and recent reports from England tend to bear out this statement.

**Vitamin Therapy.**—The ingestion of large amounts of vitamin B has been recommended by Fletcher who believes that the sluggish and atonic colon so often present in these cases is due to vitamin B deficiency. He claims that the ingestion of this vitamin improves the tone of the colon which in turn, by improved elimination, helps in the cure of the arthritis. Snyder and Fineman, in a discussion of Fletcher's paper at the conference of the Committee on Arthritis in Milwaukee, in 1933, stated that they could not substantiate Fletcher's results since they had been unable to duplicate his roentgen evidence of the colon changes. A general tonic effect was noted in the patient after excessive feeding of vitamin B, but no beneficial local effect in the arthritis.

The excessive ingestion of vitamin C has been advocated by Rinehart and his associates<sup>29</sup> because, by its deprivation, they were able to produce an arthropathy in guinea-pigs which they considered to be very similar to chronic arthritis in the human. It was shown that a superimposed infection usually accentuated the production of the arthritis. With adequate vitamin C nutrition, however, arthropathy could not be produced in the guinea-pig even when it was subjected to coincidental infection. Some of Rinehart's arthritic patients showed clinical evidence of vitamin C deficiency. In spite of these interesting findings, Faulkner<sup>30</sup> and Bauer concluded that vitamin C deficiency plays no rôle in chronic arthritis. Bauer's patients

who adhered to a high vitamin C diet for from three to five years were no more improved than patients not so treated. Although Rinehart believes that his animal experimental lesions closely resemble those of arthritis in the human, other workers have failed to note the close similarity and doubt the accuracy of his test for vitamin C deficiency.

Dreyer and Reed<sup>31</sup> reported in 1935 that they had placed 34 patients with atrophic arthritis on massive doses of vitamin D and that 25 were improved. They noted also some improvement in patients with hypertrophic arthritis. In a few instances this improvement was noticeable after a week; in other patients six months' treatment was required. The patients were given 200,000 U.S.P. or international units of vitamin D daily for one month. If relief was noted, the dose was reduced to 50,000 or 60,000 each week. Toxic symptoms, consisting of nausea, frequency of urination, diarrhea, vomiting and abdominal pain, occurred in a small percentage of cases. To combat this toxicity, the drug was discontinued. We are at present testing this form of treatment in a group of 30 patients. Most of these patients have shown a general tonic improvement during the past year, but the arthritis has thus far remained almost unchanged.

**Bilirubin and Bile Salts Intravenously.**—Recent reports by Hench<sup>32</sup> and Thompson and Wyatt<sup>33</sup> tend to indicate that the liver is an important organ in the problem of chronic arthritis. Hench describes 31 cases that were absolutely free of all arthritic symptoms during and for several weeks or months subsequent to the onset of an intercurrent jaundice. Thompson and Wyatt report that they were apparently able to cure intractable cases of chronic arthritis by an artificially induced jaundice, through intravenous administration of large doses of bilirubin and bile salts.

### CONCLUSIONS

1. Treatment to be successful must be adapted to the individual patient.
2. Beneficial results are rarely observed in arthritis in less than three months: many require from one to three years of persistent treatment. The physician must exercise sound judgment in deciding which foci of infection are to be removed and

the time and sequence of their removal. He must study carefully in each case the type and amount of medication to be given. Many failures in the treatment of arthritis can be attributed to insufficient attention to details and lack of vigorous attack. Such drugs as cinchophen, tolysin, aspirin, gold salts, and sulfur must be carefully controlled but given to the point of tolerance.

3. The physician must endeavor to overcome the mental depression of the average patient suffering from this disease. In spite of the fact that we are still in the dark as to the underlying cause of chronic arthritis and are unable for that reason to direct treatment against the specific etiologic factors, diligent application of our present knowledge will often result in a satisfactory or even at times spectacular improvement in the patient's condition.

4. Inasmuch as there is as yet no absolute evidences that rheumatoid arthritis and osteo-arthritis are distinct entities of different etiology, the physician must bear in mind when treating osteo-arthritis as in rheumatoid arthritis, the possibility of the presence of foci of low-grade infection as well as of intestinal toxemia. He must also regulate metabolic and glandular disturbances in addition to carrying out the generally accepted methods of treatment of arthritis, such as reduction in weight, elimination of trauma, improvement of circulation and the institution of an adequate amount of rest.

5. In the entire field of medical practice there is no more grateful patient than the sufferer from arthritis who has been relieved of his symptoms and restored to economic usefulness.

## CLINIC OF DR. PHILIP D. WILSON

### HOSPITAL FOR RUPTURED AND CRIPPLED

---

#### SURGICAL RECONSTRUCTION OF THE ARTHRITIC CRIPPLE

WHILE the general and systematic treatment of chronic atrophic arthritis is largely a medical problem, certain aspects of the disease have always been and will continue to be of great interest to the orthopedic surgeon. These have to do chiefly with the prevention and correction of joint deformity during the active phase of the disease and with measures to obtain restoration of function in badly damaged joints when the disease has reached an inactive stage. It is the latter part of the therapeutic problem that I shall attempt to consider here. While it represents but one small phase of the large problem of what to do for the arthritic cripple, it is an important one in view of the many brilliant results that have been obtained in the past and also one that is poorly understood and frequently neglected by the medical practitioners who stand in closest relation to the patients.

May I make clear at this point that between the two great types of arthritis, the atrophic and hypertrophic, I shall confine my discussion entirely to the former. While hypertrophic arthritis presents its own special questions and is frequently amenable to surgical treatment, there is no doubt that atrophic arthritis represents the greater part and the more complicated part of the therapeutic problem and we shall have enough to occupy us if we consider it alone. Let me remind you that in atrophic arthritis, otherwise known as rheumatoid, proliferative or infectious arthritis, the characteristic pathologic changes are of a proliferative nature, first affecting the synovial membrane with secondary invasion of the articular cartilage. The process is definitely ankylosing in tendency and for this reason

prolonged immobilization is dangerous and should always be avoided.

In atrophic arthritis we have to deal with a general disease and health problem in addition to the local problem of relieving a cause of disability. Fortunately there are encouraging features of the disease which should be recalled along with the discouraging one. Every physician who has had much experience with arthritis has seen patients in whom, for one

Fig. 110.—Case 1. Chronic synovitis of left knee A, Preoperative B, After synovectomy.

reason or another, the disease has been arrested and who have remained in good health for years. Such patients may be terribly crippled, confined to bed or to wheel chairs, and unable even to feed themselves, but the essential point is that their condition has remained stationary for many years or, in other words, that the arthritic fires have been extinguished and that their disabilities are due to joint damage which the healing processes of the body have been unable to repair. In this connection it must always be remembered that abundant experimental evidence exists to show the limited healing powers of

joints in general and of articular cartilage in particular, especially in adults.

**Surgical Obstacles.**—No problem is more appealing than that of the rehabilitation of arthritic cripples, but unfortunately the surgical attack upon the disabled extremities is attended by many difficulties and their solution calls for the soundest judgment and highest skill. The chief difficulty is constituted by the fact that usually there is multiple joint involvement and

Fig. 111.—Case 2. Arthritic contractures of both knees. Range of motion before operation. (Long scar from incision of removal of fascia for arthroplasty of elbow.)

not one but several operations must be performed in order to obtain relief. These must be done at properly spaced intervals, and each carried through with its appropriate after-treatment before the goal is attained. Each link must be forged separately and then welded together before the chain is complete, and one defective link may mean the failure of the entire chain. Nevertheless what has been done for some can also be done for others. Helpless arthritic cripples have been trans-

formed into active, independent individuals, in some instances able to contribute to the income of the family. Improvement of greater or lesser extent may be obtained in a large number of properly selected arthritic invalids.

The surgeon must attempt to answer the following questions in relation to the individual patient:

1. Is the arthritis quiescent?
2. Is the patient's physical condition good enough to warrant undertaking an extensive surgical program?
3. Is the expected functional gain likely to be worth the effort, taking into consideration the patient's age, physical condition, and the series of operations necessary?
4. Is anything to be gained by delaying the operation and by advising further treatment of any kind?
5. Are the patient's morale and willingness to stand pain such as to offer promise of the necessary cooperation in the after-treatment?
6. Does the hospital where the patient is to be treated possess all the necessary facilities for successful treatment?
7. Can arrangements be made for the necessary treatment and surgical supervision after the patient leaves the hospital?
8. Has the patient provided an adequate budget to see the treatment through from beginning to end? (Under present conditions often an insurmountable obstacle.)

**Surgical Objective.**—The surgeon must have a clear idea of the objective in view and must not be led away from the pursuit of one goal to that of another before the first is reached. On account of the great variation both in the extent of the involvement and in the joints that are principally affected, this is likely to happen unless he clearly differentiates the arm problem from the leg problem:

1. The arm problem has to do with restoring the use of the arms and particularly to permit the patient to eat, dress and perform the various acts of toilet and personal care without assistance. When the elbows are ankylosed and the fingers and wrists stiff, the patient is practically as helpless as if both arms had been amputated and, if possible, relief should be given.

2. The leg problem has to do with restoring the patient's ability to move about without assistance. It is not sufficient

only to restore the power of locomotion but the patient must also be able to get up from a chair and to sit down again unaided.

The solution of either of these problems constitutes an end in itself and the gain justifies the series of procedures which may be necessary. When both the arms and the legs are disabled, the solution of the arm problem should be attempted first and the effort is justified even though nothing be attempted for the legs. The surgeon must avoid operations that do not

Fig 112.—Case 2. After posterior capsuloplasty of both knees.

lead to either one or the other of these goals and that might prove of theoretical or esthetic benefit only.

**When to Operate.**—It needs to be emphasized again, for fear of misunderstanding, that the rôle of surgery in the treatment of chronic atrophic arthritis comes only after the disease has reached a stage of quiescence and has remained so for at least six months. Even this is too short a time to be free from the danger of recurrence, but if this does occur there is likelihood that it can be held in check by proper treatment. Physicians must learn to differentiate the inactive from the active stage. In many cases this is easy from the history and the

examination; in other cases it may be difficult. The chief cause of error is the persistence of pain, the physician being unable to differentiate the pain caused by stretching of adhesions, movement of a fibrosed capsule, or strain resulting from attempted use of a damaged joint from that caused by actual arthritic swelling and inflammation. Careful examination of the joint and analysis of the maneuvers that reproduce the pain will usually yield evidence upon which an opinion may be formed. When doubt persists the matter can only be determined by observation over a period of time.

Fig. 113.—Case 3. Multiple atrophic arthritis. Motion in right elbow following arthroplasty.

**Operative Procedures.**—A variety of operative procedures may be employed for the relief of the disabilities of atrophic arthritis. These include synovectomy, capsuloplasty, osteotomy, arthrodesis and arthroplasty. The selection of the appropriate procedure depends upon the estimation of the nature and severity of the pathologic changes in the affected joint and upon the appraisal of the patient as an operative risk. The strain of an operation is in some ways akin to that of participating in an athletic contest and no patient who has been inactive for years is a good operative risk. Minimal procedures should be selected and one should avoid the mistake of attempting more than one operation at a time. Nevertheless, it is

impossible to avoid all danger in the rehabilitation of the arthritic cripple and one is sometimes confronted by the alternative either of going ahead at considerable risk or of abandoning the attempt altogether. In such a case the decision should be left to the patient after frankly presenting both sides of the question to him.

**Synovial Hypertrophy.**—Hyperplasia of the synovial membrane is a characteristic part of the pathologic process of atrophic arthritis and may persist even after the disease has become inactive and constitute a cause of disability. The membrane becomes thickened and is thrown into folds and villi which may cause mechanical interference with joint function or become pinched between the articular surfaces with the production of pain. Synovial hypertrophy is not infrequently associated with chronic effusion or hydrops, the scarred and thickened membrane not permitting the normal drainage or interchange of fluids. The condition is seen most typically in the knee joint where, because of the large synovial area and the superficial position, it is more evidently a cause of trouble than elsewhere.

Tenderness in the region of the infrapatellar fat pad, pain and restriction of motion on attempt to completely extend the knee, are not infrequent symptoms. Upon x-ray examination the joint cartilage shows no damage or only slight damage and the changes are chiefly thickening of the soft parts.

In such cases when supportive measures have been tried without result, relief may be obtained by the operation of synovectomy. It has been shown by experiments upon animals that excision of the synovial membrane is followed by the formation of a new synovial layer developed by metaplasia of the surrounding connective tissue. The operation should be performed cautiously and only in selected cases as experience has shown that when performed indiscriminately there may be a diminution of joint motion or a recurrence of pain. I have not been impressed from observation of my own and other surgeons' cases that there is any evidence to support the claim that synovectomy rids the body of a focus of infection which may serve to propagate the disease in other joints.

Postoperative splinting is not generally required after synovectomy, large compression dressings being sufficient. Active

movement is encouraged beginning a few days after operation. Weight bearing is usually permitted at the end of three to seven weeks.

**Flexion Deformities of the Joints.**—Joint deformities in atrophic arthritis are chiefly the result of the patient's efforts to obtain relief of pain during the active stage of the disease by flexing the joints and maintaining them in positions of relaxation. Complete extension, because it puts tension upon the ligaments, is the more painful motion and the one that is chiefly avoided. The joint capsule which is thickened and infiltrated adapts itself to the flexed position and loses its exten-

Fig. 114.—Case 3. Motion in left knee following arthroplasty.

sibility; the muscles become contracted, and unless measures are taken to overcome it the deformity becomes fixed. The longer it is allowed to persist, the more permanent the character of the contraction. If the arthritis becomes inactive and healing occurs without much articular damage, the joint still remains partially flexed because of fibrotic changes in the capsule. If the arthritic process continues the articular cartilage is destroyed, the synovial pouches become obliterated and adhesions form between the layers of pannus covering the ends of the bones. The joint still remains flexed but there is now a condition of fibrous ankylosis and in time this may go on to bony ankylosis.

It is necessary to point out that flexion deformities of the joints almost always represent errors and neglect of previous treatment. While one must admit that the difficulties in the way of prevention are many in a disease like atrophic arthritis, which lasts through many years and eventually passes through a good many different medical hands, they are not insurmountable if every physician having to do with the condition exercises the necessary foresight. The removal of pillows from under knees, the use of adhesive extension from time to time to the

FIG. 115.—Case 3. x-Ray following arthroplasty of left knee.

legs, or part time splinting will prevent the need for later surgery in many of these cases.

**Capsular Contraction.**—Simple capsular contraction with but slight damage to the joint cartilage is most frequently a cause of disability in the elbows and knees. In the elbow the contracture shows itself chiefly as a limitation of extension but does not cause any great handicap as long as motion in flexion is preserved because of the fact that the arm is used chiefly with the elbow flexed. In the case of the knees, however, complete extension is necessary for locomotion and to relieve the extensor muscles of too great a burden when weight

is borne. Flexion contractures of the knees are usually bilateral and when they exceed 30 degrees usually drive the patient to a wheel chair existence.

The characteristic feature of these contractures is the preservation of motion in flexion so that the joint may be bent almost to the normal limit. It cannot be extended, however, beyond a certain fixed point. There is frequently a certain amount of posterior subluxation of the tibia on the femur but the x-ray examination shows only slight if any changes in the articular cartilage.

Numerous procedures have been devised to overcome these flexion contractures of the knees, mostly in the form of special appliances exerting traction or leverage on the leg in such a manner as not only to correct the flexion but also to overcome the posterior subluxation of the tibia. They necessitate prolonged fixation of the joint which is always unwise in atrophic arthritis even in the quiescent stage. Such gain as is made in extension is usually won at the cost of pressure sores in the heels, circulatory disturbance of the feet and decreased motion of the knees. Manipulative correction is a dangerous procedure even when done gently and may easily result in a fracture because of the extreme atrophy and fragility of the bones. In the quiescent stage it is rarely advisable because of the long-standing and fixed character of the deformities and in the end open procedures are generally to be preferred.

After trial of many of these methods I became dissatisfied with their results and more than ten years ago began to resort to operative freeing of the capsule. This operation has given good results in properly selected cases and I have continued to use it. The technic of this operation has been described under the name of posterior capsuloplasty and, in brief, consists of making an incision over the lateral aspect of the knee, dividing the iliotibial band of the fascia lata, lengthening the biceps tendon, both of these structures being contracted, and then opening the posterior compartment of the knee and stripping away the attachments of the posterior capsular ligaments to the femur. It is then usually possible to manipulate the knee into complete extension in which case after closure of the incision a plaster casting is applied. Otherwise extension is applied by means of a wire passed through the os calcis.

Since only the soft parts are sectioned during the operation, it is possible to begin movement at the end of two to three weeks. The casing is split and removed during the daytime to permit exercise but is reapplied at night. Walking with a brace is permitted at the end of four to five weeks. The use of a night plaster is continued for upward of six months in order to prevent any danger of a recurrence of the contracture.

**Capsular Contraction with Joint Damage.**—When the arthritis has progressed a stage farther than that just described

FIG. 116.—Case 4 Bony ankylosis of both hips. Patient unable to sit, stand or walk with any comfort.

the treatment becomes more complicated because of the added factor of considerable articular damage. Here again such deformities are of chief interest in relation to the knees because the largest gain is to be obtained from their correction. Examination of such knees shows a smaller amount of free motion than in the simple capsular contractions and the restriction is not only in extension but also to a lesser degree in flexion. The motion may be free from pain and of sufficient extent to be useful if it only occurred in an arc where it would be of greater functional value. The x-ray examination generally reveals

narrowing of the joint space but the amount of cartilaginous damage is not extreme.

On the whole, the simplest solution of this problem is to perform a supracondylar osteotomy of the femur and to secure complete extension of the knee at the cost of angulating the femoral fragments. The drawback to this operation is that it requires eight weeks' immobilization in plaster and, as pointed out previously, is likely to be attended by some diminution in the range of motion. This has been confirmed to a certain extent by the experience with certain cases and while the decrease has not been serious it has led me to be cautious and to restrict the use of osteotomy to deformities in which the indications are very definite.

**Painful Joints.**—Extensive damage to the joint cartilage may of itself be a cause of painful function without necessarily causing marked limitation of joint motion. Pain of this type is incurred only on use of the joint and is relieved promptly by rest. If the patient persists in using the joint there is reaction in the form of swelling and effusion. Clinical examination might easily lead one to conclude that the trouble was due to proliferation and thickening of the synovial membrane but the cue to the real difficulty is obtained from the *x*-ray examination which shows extensive changes in the articular surfaces. There is narrowing of the cartilage space, irregularity and eburnation of the bony surfaces and considerable productive change of the joint margins. Such pathologic changes are incompatible with good joint function and one is justified in considering a surgical remedy. Too often under these circumstances the surgeon jumps to the conclusion that fusion of the painful joint offers the best solution.

I do not agree with this opinion, and in general believe the resort to fusion operations in atrophic arthritis is ill advised. This disease is subject to recurrences of activity from time to time and one can never predict with certainty that other joints may not be involved at some later time. One should always aim to preserve or increase motion in arthritis instead of eliminating it. I have frequently seen arthritic cripples in whom the reconstructing problem was rendered infinitely more difficult because of a previous fusion operation. The articulations adjacent to the fused joint are rarely normal and the

patients have usually walked awkwardly and used the limbs poorly. I have fused some arthritic knees but have never done it without later regrets.

Painful joints must be relieved but this can usually be accomplished in other ways than by fusion. The cause of the pain must be carefully sought. If due to synovial hypertrophy or tabs, partial or complete synovectomy may be the remedy. If the result of ligamentous strain, the faulty weight-bearing lines should be corrected and the limb adjusted in proper position. This may necessitate the use of various types of braces

Fig 117.—Case 4 Robert Jones' pseudarthrosis of both hips. Motion restored.

or the performance of an osteotomy. If it is due to articular damage, then partial or complete arthroplasty may be required.

**Ankylosis.**—Ankylosis of one or several joints is the common late result of unchecked atrophic arthritis. With the development of multiple ankyloses, the active arthritis usually is extinguished as if it lacked further fuel to keep it burning. The patients are completely helpless and dependent and the effect is the same whether the ankylosis is fibrous or bony. The only remedy for ankylosis is the operation of arthroplasty, and in these ossified cripples not one but several arthroplasties may be required if worth-while results are to be obtained.

Arthroplasty is an operation to construct a new joint. If bony ankylosis is present the bones are divided at the level of the old joint, the ends trimmed and smoothed to simulate the normal articular configuration and the surfaces are then covered with a sheet of fascia lata removed from the thigh and carefully stitched in place. If the ankylosis is fibrous the joint surfaces are removed and fascia lata interposed in exactly similar manner. The fascia serves a double purpose; first, of preventing recurrence of ankylosis by forming an intervening barrier between the raw bone ends, and, secondly, of forming

Fig. 118.—Case 4. Range of abduction following Jones' pseudarthrosis

the foundation for the development of a pseudarthrosis such as is seen when a fracture fails to unite by providing a nidus of fibrous tissue from which granulation tissue grows to obliterate the joint space. Different methods must be employed to deal with the different joints but it is unnecessary to bother you with details of operative technic or to explain the individual variations of different surgeons, as I am chiefly concerned with showing what may be done. It is sufficient to state that prolonged and patient after-care is necessary, which requires the full cooperation and determination of the patient and that with-

out these the result may be failure, irrespective of how skillfully the operation is performed.

My first operations for the relief of ankylosis in atrophic arthritis were performed approximately fifteen years ago and were accompanied by misgivings because of the warnings of experienced surgeons that such operations were inadvisable in this disease. Tragedies have not resulted; there have been but few complete failures and on the whole the results have exceeded expectations. This experience has tended to make me broaden the indications for its use and I do not hesitate to advise it now in cases which I would not have considered operable by former standards. Even when there is later recurrence of the arthritis the new joint produced by arthroplasty retains its good function and shows no evidence of involvement. The elbow and jaw give the best results, the knee the next best, and the hip follows closely after. Weight bearing after arthroplasty of the knee or hip should be postponed until the end of twelve weeks and then only with brace protection. Arthroplasty of the finger joints is a tedious procedure but worth-while results can be obtained when it is performed with proper technic.

Multiple arthroplasties have been performed at different times in the same patients with, in some instances, remarkable functional improvement. In case of bilateral ankylosis of the elbows double arthroplasty may be counted upon to give good results. In case of bilateral ankylosis of the knees it is usually sufficient to perform arthroplasty of a single knee although in 2 patients I have done double arthroplasty with fair results. In case of ankylosis of both hips double arthroplasty is frequently necessary, and I have seen the result in the first hip improved after doing the second. In case of ankylosis of both hips and both knees the attempt should be made to restore motion in one hip and in the opposite knee. Later it can be decided whether something should be attempted for the second hip.

In a complicated problem of this type Jones' operation for creating a pseudarthrosis of the hip presents certain advantages. The neck of the femur is divided at its base and the greater trochanter with its attached muscles is split off and turned up to cover the raw bone surface of the neck after the

excision of a generous portion of the bone.' The neck thus serves as a buttress or shelf to prevent upward displacement of the shaft. The operation may be depended upon to restore movement of the hips although at the expense of some loss of stability.

**Conclusion.**—In what has gone before I have tried to sum up clinical impressions obtained from the study of a group of more than 125 patients with approximately 200 operations performed in the last fifteen years. I have attempted to show that surgical measures are frequently required to carry on, and complete the work of rehabilitation of the arthritic cripple, but that the field of surgery is strictly limited and should never begin until after the disease has been rendered inactive by general medical treatment. The treatment is costly both in time and effort but worth-while rewards are obtained when patients may again begin to take care of themselves or may leave their wheel chairs and begin to walk. It is for the physician to learn the possibilities of surgical reconstruction and to open up for many patients new avenues of hope.

## CLINIC OF DR. SOLOMON FINEMAN

SEA VIEW AND MT. SINAI HOSPITALS

---

### THE RÔLE OF THE ROENTGENOLOGIST IN THE DIAGNOSIS AND TREATMENT OF CHRONIC ARTHRITIS

The chronic arthritides form the following 9 clinical groups:

1. Atrophic. Synonyms: rheumatoid, chronic infectious of unknown etiology, proliferative.

In this group belong the arthritides discussed by various authors under the following names: chronic polyarthritis, ankylosing polyarthritis, nonspecific nonsuppurative focal arthritis deformans, spondylarthritis, spondylarthritis ankylopoietica, ankylosing spondylitis, spondylitis ossificans ligamentosa, spondyloze rhizomêlique, Marie-Strümpell disease, Pierre-Marie-Strümpell disease, spondylitis muscularis (Bechterew type), spondylitis senilis, and juvenile polyarthritis (Still's disease).

2. Hypertrophic. Synonyms: osteo-arthritis, degenerative or senescent, non-ankylosing.

In this group belong spondylitis deformans, Schmorl's deforming spondylosis, spondylosis deformans, morbus coxae senilis, Heberden's nodes, and osteochondritis desiccans.

3. Mixed, atrophic (rheumatoid) and hypertrophic (osteo-arthritis) arthritis occurring in the same patient.

4. Specific infectious: gonorrheal, syphilitic, tuberculous, typhoid, pneumococcic, staphylococcic, streptococcic, meningococcic, influenzal, and those due to trichinosis or dysentery bacillus infections.

5. Neuropathic: Charcot joint, syringomyelia, and posthemiplegic.

- 6 Joint changes due to faulty constitutional processes as seen in gout, scurvy, hemophilia, serum allergy, intermittent hydrarthrosis, Paget's disease, hyperparathyroidism, food allergy, climacteric, ovarian and thyroid disturbances.

- 7 Traumatic: endogenous or exogenous.

- 8 Neoplastic: benign, primary malignant, and metastatic.

- 9 Unclassified

### ROENTGENOLOGIC DIFFICULTIES IN CLASSIFYING ARTHRITIS

It is well to remember that clinical arthritis even though of long standing may not show roentgen evidence of joint change in many cases. The disease process may be limited to

the soft tissues and the changes may be insufficiently pronounced to be visible on the roentgenogram.

In typical atrophic (rheumatoid) arthritis, the following changes occur early and can be recognized roentgenologically: proliferation of the synovial membrane, thickening of the joint capsule, and joint effusion may become apparent as increased density of the soft tissues, with visible distention of the joint capsule and displacement in the knee, for example, of such joint structures as the fat pads and patella.

Later there occurs atrophy of the bony tissues adjacent to the joint with partial or total destruction of the cartilage, and consequent narrowing or obliteration of the joint space. Erosion or marked destruction of the articular bony margin, with formation of loose bodies occasionally, and with partial or complete dislocation of the articulating bones may follow. The end-result is fibrous or bony ankylosis. This constitutes the classical roentgen evidence of atrophic (rheumatoid) arthritis.

In atrophic (rheumatoid) spondylitis there occur, early, irregular calcifications of the ligaments. The process may progress, resulting in bony ankylosis of the entire spine. The intervertebral disks may be somewhat narrowed but they are not destroyed. The vertebral bodies show atrophic changes, and often lipping. The articulating facets may show atrophic changes and may fuse.

In typical hypertrophic arthritis (osteo-arthritis), the early roentgen changes are seen as increased densities due to localized synovial membrane proliferations. There may be slight periarticular lipping and slight atrophy of the cancellous bone close to the joint. Later the lipping becomes more prominent, and the joint space usually shows some narrowing. Later on the joint space may be completely obliterated with approximation of the bony surfaces. This depends on the degree of cartilaginous destruction. Hyperostosis, with pronounced spur formation is common, occasional bony bridging occurs. The articular bone shows sclerosis and may later show erosions of the articular surface with cystic destruction of the cancellous bone. Loose bodies, due to detached periarticular chondro-osteophytes, may be seen. Subluxation may occur as well as calcification of the joint capsule and ossifying periostitis of the shaft near the joint. In rare cases ankylosis occurs.

In hypertrophic spondylitis (osteo-arthritis) the ligaments do not usually calcify. The vertebral bodies are not destroyed but on the contrary show increased sclerosis. Bony spurs form early, and are prominent, and segments of the spine may be fixed by mechanical interlocking of the exostoses. The intervertebral disks show destructive changes. The facet spaces show narrowing and there is sclerosis of the articular facets.

The chronic arthritides of the mixed group show a mixture of the roentgen changes described under the atrophic (rheumatoid) and hypertrophic (osteo-arthritic) form of arthritis. The changes of one type may predominate and almost completely mask the other type. Often the picture is extremely confusing.

The arthritides of the remaining groups, with the exception of joint neoplasms, show the same basic roentgen changes. They do not present characteristic pathognomonic findings. The changes may be atrophic, hypertrophic or both depending on the duration of the disease, the joint involved, the age of the patient and many other factors. In chronic arthritis of every type the roentgenologist is often faced with insuperable difficulties when he attempts etiologic classification solely on the basis of roentgen findings. The pitfalls are numerous and mistakes in diagnosis are frequent.

Some of the inherent difficulties of the subject may become evident from the following review of the literature:

Two types of arthritis may be present in one and the same patient (Scott, 1932<sup>1</sup>).

Spackman<sup>2</sup> (1936) states that "as pointed out by Osgood and others we can not say that both processes (atrophic and hypertrophic arthritis) do not occur simultaneously in the same patient or even in the same joint."

Rigler and Wetherby<sup>3</sup> (1933) failed to observe, in their group of cases, hypertrophic changes in any elbow or shoulder, and only few spine and knee cases with atrophic changes. They suggest that the type of joint reaction may be due to location rather than to its etiology. In 21 per cent of the joints which had been afflicted more than five years there were no roentgenographic abnormal changes. A negative roentgenogram even late in the disease is of little significance.

There are cases on record in which roentgenograms were made early in the process and the condition classified as atrophic

arthritis, and in which later the diagnosis was changed to hypertrophic or mixed arthritis (Wetherby,<sup>4</sup> 1932).

The end-stage of both atrophic and hypertrophic arthritis may be bony ankylosis (Osgood,<sup>5</sup> 1930; Baetjer and Waters,<sup>6</sup> 1921).

Osgood<sup>5</sup> (1930) believes that occasionally both atrophic and hypertrophic arthritis may exist in the same patient, though this is relatively rare.

Brailsford<sup>7</sup> (1935) calls attention to the fact that the shoulder joint is subject to rheumatoid (atrophic) arthritis, but relatively rarely to osteo-arthritic (hypertrophic) changes.

Wetherby<sup>4</sup> (1932) calls attention to the fact that the shoulder joint, for instance, shows in nearly all cases atrophic changes, while in the knee hypertrophic changes are much more common. He stresses the significance of this in view of the involvement of the knee and shoulders, in arthritic persons of all age groups, in about the same incidence.

Localized atrophic arthritis (rheumatoid) of the spine which frequently responds to removal of foci of infection (teeth, sinuses, gallbladder and gastro-intestinal tract), may later show lipping of the margins, pointing of the articular facets, ossification of the anterior ligaments, destruction of one or more intervertebral disks and irregularity and sclerosis of the opposing vertebral surfaces (Brailsford,<sup>7</sup> 1935).

Rigler and Wetherby<sup>3</sup> (1933) conclude that the end-result of the proliferative form of arthritis (atrophic) is a combined destructive and hypertrophic reaction.

Doub<sup>8</sup> (1936) points out that atrophic and hypertrophic arthritis are frequently seen as mixed types, and it is often difficult to say which type antedated the other. In some cases it is also difficult to distinguish between the two types from pathologic specimens either by gross or microscopic examination. They are also in some instances indistinguishable from other types of arthritis at certain stages of their course.

In many cases there is grafting of one form of arthritis on the other, as for example where fusion of bones with ankylosis is found associated with well-developed spurs in which bony trabeculae are plainly visible. In other cases predominant hypertrophic changes in certain joints and unmistakable signs of atrophic changes in other joints were found in the same patient (Spackman,<sup>2</sup> 1935).

Allison and Ghormley<sup>9</sup> (1931) found in their study of joints by gross and microscopic examination that the distinction between the proliferative (atrophic) and degenerative (hypertrophic) forms was not always distinct.

Changes in joints due to various etiologic agents at times simulate each other (Wetherby,<sup>4</sup> 1932).

A typical case of atrophic arthritis (spondylitis deformans of the Marie-Strümpell type) may be indistinguishable from a gonorrheal infection (Knaggs,<sup>10</sup> 1925).

Hypertrophic arthritis (osteo-arthritis) may simulate in old persons the reparative stage of tuberculous, gonorrheal, syphilitic and pneumococcic arthritis (Gelber,<sup>11</sup> 1934).

Pepper<sup>12</sup> (1929) describes a chronic deforming gonorrheal arthritis with both hypertrophic and atrophic changes which is not to be differentiated as to cause from the roentgenograms alone. He also describes a type of gonorrheal arthritis with punched-out areas in the bone which resembles gout. He concludes by stating that gonococcal arthritis does not present a distinct roentgen appearance, but that the roentgenogram used in conjunction with the history may be of valuable diagnostic assistance.

Shapiro<sup>13</sup> (1932) and Rigler and Wetherby<sup>3</sup> (1933) state that gonorrheal arthritis may be indistinguishable from atrophic arthritis.

Charcot's hip and shoulder joints and spine may show atrophic and hypertrophic phases. The atrophic type may be simulated by tuberculosis of the spine (Brailsford,<sup>7</sup> 1935).

Baetjer and Waters<sup>6</sup> (1921) emphasize that in tuberculous spondylitis there is no evidence of new bone production.

In contradiction of Baetjer and Waters' statement that new bone formation does not occur in tuberculous spondylitis, and despite this general belief, areas of new bone production around tuberculous vertebrae are not uncommon. In rare cases tuberculous spondylitis may imitate deforming spondylosis (hypertrophic) (Freedman,<sup>14</sup> 1934).

In old age, tuberculous arthritis may be mistaken for septic or hypertrophic arthritis (Holmes and Ruggles,<sup>15</sup> 1936).

Pomeranz<sup>16</sup> (1933) states that contrary to opinion an early or positive diagnosis in tuberculous arthritis is no easy task, and that an accurate interpretation is extremely difficult. The

roentgenogram is but a record of the disease at a given moment. Synovitis, periarticular swelling and atrophy of bone are common to all arthritides, and are of limited value in the diagnosis of tuberculous arthritis. Atrophy of the bone is usually marked, but sclerosis and bone production occur in tuberculosis, even in the absence of a mixed infection.

The punched-out areas in the epiphyses representing the presence of tophi, are not pathognomonic for gout. They are often present in atrophic arthritis (chronic proliferative, rheumatoid) (Wyatt,<sup>17</sup> 1933).

Holmes and Ruggles<sup>15</sup> (1936) state that in early stages of gout it may be mistaken for hypertrophic arthritis. With reference to tuberculous arthritis they write that in old age the disease may be mistaken for septic or hypertrophic arthritis.

Shapiro<sup>13</sup> (1932) claims that the supposedly typical punched-out areas of bone in gout are commonly seen in atrophic arthritis.

The cavities noted in the head and neck of the femur in many of the so-called "osteo-arthritic hips" (hypertrophic) may be of gouty origin. When gout attacks a major joint there are no radiographic changes of diagnostic value (Scott,<sup>1</sup> 1932).

Hench<sup>10</sup> (1937) writes that he is unaware of any proved case of gouty spondylitis in the literature for many years. It has been his experience that acute gout practically never involves joints of the torso, namely, those of the spinal column, hips and shoulders. Thannhauser, Pratt, Monroe and Lichtwitz (quoted by Hench) had never noted spinal involvement in any of their cases of gout. Monroe and Lichtwitz had never, and Thannhauser had rarely encountered involvement of the hips. However, Talbot (quoted by Hench) had under observation a patient with tophaceous gout and gouty arthritis of several joints whose roentgenograms gave evidence of gouty erosion in the sacro-iliac joints, and Bauer stated that on postmortem examination recently he had found urate deposits in the vertebrae of 1 case.

Keefer and Myers<sup>20</sup> (1933) write that there is no absolutely characteristic picture present in all cases of hemophilic arthritis. The chronic lesions may resemble gout, degenerative (hypertrophic), or tuberculous arthritis (Doub,<sup>8</sup> 1935). Late

in hemophilic arthritis roentgenograms may simulate those in tuberculous, atrophic or other types of arthritis (Kahn, Rypins, Solis-Cohen and Levine, quoted by Hench<sup>18</sup>).

Doub and Davidson<sup>21</sup> (1926) say that in early hemophilic arthritis there are no destructive changes. In these cases there is effusion of blood into the joint, thickening of the joint capsule, and lipping similar to hypertrophic arthritis. In the advanced stages there are destructive changes both in the joint cartilage and bone. There may be punched-out areas in the epiphysis, destruction of the articular surface and blood in the synovial cavity.

In traumatic arthritis the picture of capsular distention due to increase of synovial fluid differs little from the first stage of an infectious process of known etiology. If continued over a long time, destructive and productive changes occur in the same joint (Gelber,<sup>11</sup> 1934).

The changes in traumatic arthritis, due to injury are synovial thickening, necrosis of the cartilage, with narrowing of the joint space and bone proliferation. This type of arthritis simulates hypertrophic arthritis (osteo-arthritis), and it is difficult to distinguish the two types roentgenographically (Doub,<sup>22</sup> 1933).

It should be evident from this survey that precise classification of the arthritides based solely on roentgenographic evidence is too often unsatisfactory to be of much aid to the clinician.

Rigler and Wetherby<sup>3</sup> (1933) in their study of 60 cases of chronic polyarticular arthritis observed that a large number of arthritic joints may give no abnormal roentgen findings throughout the course of the disease. They attempted to divide their cases roentgenologically into "atrophic," "hypertrophic" and "infectious" groups. Most of the infectious cases occurred in the later decades of life and with the greater duration of the disease, indicating to the authors that the combined destructive and hypertrophic reaction of the "infectious" type is simply a more extreme and older phase of atrophic arthritis. They concluded that roentgenologic attempts to differentiate between atrophic and "infectious" arthritis should be abandoned, and that for roentgen purposes chronic arthritis should be divided into atrophic, hypertrophic and mixed.

Scott<sup>23</sup> (1935), however, divides the hypertrophic type of arthritic cases into infectious and noninfectious groups, the basic differences in his classification of joints being as follows: (1) decalcification of the skeleton is peculiar to rheumatoid arthritis, (2) loss of cartilage with the formation of osteophytes is associated with the osteo-arthritic group, (3) loss of cartilage with early sclerosis of those bones entering into the formation of the joint, usually of a single finger, denotes a chronic infective arthritis, while (4) the "punched-out" areas seen on the edge of the articular surfaces indicates the presence of gouty deposits, which are characteristic of gouty arthritis. He reminds us, however, that it is possible to get a mixed or dual arthritis, or even 3 types of arthritis in a single patient.

Aldred-Brown and Steven<sup>24</sup> (1936) attempted to follow Scott's classification in 154 consecutive cases but did not feel justified in separating cases of rheumatoid arthritis from those of chronic infective arthritis. Strangeways<sup>25</sup> concluded long after many years of investigation that it was impossible by any known method, including the radiologic, to distinguish between the different types of arthritis. Hench (1936) regards Gelber and Goldberg's roentgenologic classification into "infectious" and "atrophic" as unnecessary. Spackman<sup>2</sup> (1936) writes that the roentgenologist in interpreting his findings must weigh and consider carefully both the clinical and the roentgen features of the particular case in question. Otherwise the result is too often a roentgenologic report which is not only of no direct assistance to the physician but may be grossly misleading. Occasionally he has not been able to decide from the roentgen evidence alone whether the hypertrophic or atrophic variety is present. The roentgenologist should not be guided solely by those changes which he can see on the roentgenograms.

Wyatt<sup>17</sup> (1933) states that the pathology of early atrophic arthritis explains the absence of early roentgen findings other than those that characterize the beginning of all joint disease. Formerly it was considered the function of the roentgenologist to confirm diagnoses of tuberculosis of the hips, spine and so on, but such is no longer the case.

Many others admit that attempts to classify the arthritides on purely roentgenologic data lead to failure and often misguide the clinician. Among this group we may name Moore<sup>26</sup>

(1929), Wetherby (1932), Morrison and Kuhns<sup>27</sup> (1936). Fisher<sup>28</sup> (1936), and Holmes and Ruggles<sup>15</sup> (1936). Most of the literature alludes to the great help obtained by the roentgen method of examination; some even state that the exact type of arthritis can be ascertained in this way but that this is true only in some cases.

#### DIFFICULTIES IN DETERMINING THE ETIOLOGY OF ATROPHIC (RHEUMATOID) AND HYPERTROPHIC ARTHRITIS (OSTEO-ARTHRITIS)

It is generally admitted that the exact etiologic agent or agents responsible for the atrophic and hypertrophic forms of arthritis are unknown. Spackman<sup>2</sup> (1935), Morrison and Kuhns<sup>27</sup> (1936) suggest the possibility of common unknown etiologic factors affecting joints differently at different age levels under different metabolic or endocrine conditions. Morrison and Kuhns<sup>27</sup> (1936) state that the belief has wide acceptance that both the atrophic (rheumatoid) and hypertrophic (osteo-arthritis) forms of chronic arthritis are often the result of similar etiologic factors. Both types may show increased density or decreased density of bone, particularly in the mixed forms of arthritis. Localized decalcification and apparent cyst formation are often observed about the metacarpal and phalangeal joints of both types of arthritis. In the past too much emphasis has been placed on the roentgenogram alone. In adult life and in the aged the differentiation of types of chronic arthritis becomes increasingly difficult. The roentgen changes, commonly called the manifestations of atrophic or hypertrophic arthritis, were frequently found to merge.

Steindler<sup>29</sup> in a study of 4339 cases of chronic arthritis of the atrophic (rheumatoid) and hypertrophic (osteo-arthritis) types found surprising relief for the first year in 20 per cent and a maintained relief in 8 per cent of the chronic hypertrophic arthritis (osteo-arthritis) cases following removal of foci of infection.

Miltner and Kulowski<sup>30</sup> (1933) considered the teeth, tonsils, paranasal sinuses, gastro-intestinal tract, genito-urinary tract and the mastoids as foci in their study of 100 cases of atrophic (rheumatoid) and of 100 cases of hypertrophic arthritis (osteo-arthritis).

In his paper on the radiographic dissection of chronic rheumatic arthritis, Scott<sup>1</sup> (1932) writes that many of the cases of spondylitis deformans (hypertrophic arthritis) show evidence of chronic infective condition or even abscess formation in the sacro-iliac joints.

In the recent British classification of arthritis one notes that hypertrophic arthritis (osteo-arthritis) may be associated with infection, that it may be secondary to atrophic arthritis (rheumatoid), that it may be secondary to trauma, or that it may be associated with disordered metabolism (climacteric, gouty, scurvy, hemophilia), or associated with organic diseases of the nervous system as in Charcot's joints or syringomyelia (Fisher,<sup>28</sup> 1936).

Miller<sup>31</sup> favors the term "osteo-arthrosis" for hypertrophic (senescent, degenerative) arthritis, to indicate lack of an infective factor in this pathologic process.

Schauffler<sup>32</sup> (1927) believes that hypertrophic arthritis is not caused by bacterial invasion and is not cured by removal of foci of infection. In his opinion the products of bacterial growth in the colon may influence the development of hypertrophic arthritis.

In 1000 consecutive cases of "lumbago" or "sciatica" Brailsford<sup>33</sup> (1932) found definite evidence of hidden sepsis in 682.

It is evident from reviewing the literature on the roentgen classification of the atrophic (rheumatoid) and hypertrophic (osteo-arthritic) forms of arthritis that the roentgenologist may find great difficulty very often in differentiating between these two disease processes.

It is also well known that the clinical differentiation between these two forms of chronic arthritis is often extremely difficult. It is clinically very important, however, to know whether the atrophic (rheumatoid) factor constitutes part of the picture in a patient with chronic arthritis, because the type of treatment chosen is often largely dependent on this clinical point.

The great difficulty in all clinical efforts to classify chronic arthritis is due to the fact that at the moment there is not available a single specific test for differentiating between atrophic and hypertrophic arthritis. The increased sedimenta-

tion rate of the red blood cells is said to be the most reliable test in the atrophic form of arthritis (Short, Dienes, and Bauer,<sup>34</sup> 1937). This test cannot be used, however, to differentiate atrophic (rheumatoid) from hypertrophic arthritis (osteo-arthritis).

As a result of this difficulty clinicians have developed a tendency to utilize to a large degree the roentgenologic examination of the joints for classification of the arthritides. Wetherby<sup>4</sup> (1932) wrote that often diagnosis of the type of arthritis present is withheld until the report on the roentgen examination is available, and then the diagnosis is made according to the changes seen in the roentgenogram.

In the writer's experience, covering a period of twelve years, during which time he has worked in close collaboration with Dr. R. G. Snyder, efforts to classify cases of chronic arthritis seen in office practice, solely on the basis of roentgenologic findings, have often met with failure. It seems that in the final analysis the clinician must still, in most instances, rely on his clinical judgment for the etiologic classification of chronic arthritis. It follows, therefore, that in a case of chronic arthritis which seems to belong to one of the three groups, known as atrophic (rheumatoid), hypertrophic (osteo-arthritic), or mixed, the clinician still must rely largely on his clinical judgment in deciding whether the discovery and eradication of foci of infection, toxemia or allergic irritation will be of clinical value in the management of the case.

#### ROENTGENOLOGIC AID IN THE STUDY OF THE ARTHRITIDES

The roentgenologist can be of great assistance to the clinician in the search for obscure foci or obscure causes of joint pain. Careful study of the teeth, paranasal sinuses, lungs, heart, gallbladder, kidneys, gastro-intestinal tract and skeletal structures may disclose foci of important etiologic relationship to the arthritic process. Roentgenologic study may bring to light abnormalities of posture, bony anomalies, soft tissue pathologic processes, pathologic processes in the organs and skeletal structures, which may immediately clarify many obscure cases of joint pain and aid materially in establishing the diagnosis.

In postural arthritis (static, endogenous, traumatic) the demonstration of flattening of the arches of the feet may explain painful ankle or knee joints and pains in the hips and lower back.

Scoliosis or abnormal lordosis, kyphotic arching of a spine segment, malalignment of the various segments of the spine in their relationship to each other or to the sacrum, may elucidate obscure cases of neck pain, backache, and pain in the chest.

Anomalies of the spine, such as congenital malformation of the articulations, dehiscence in the posterior arches of the vertebral or sacral segments and sacralization and malarticulation of the lowest lumbar vertebrae may explain the cause of painful symptoms in these regions.

In rare cases the disclosure of an old intracapsular fracture with subsequent development of bony spurs or atrophic changes and narrowing of the joint space may disclose the reason for joint discomfort.

The roentgenologic demonstration of a psoas abscess, long before there are roentgenologically demonstrable vertebral changes (Ornstein and Ulmar<sup>35</sup>), may aid in discovering an early tuberculous arthritis of the spine.

Paget's disease of the shoulder, knee and hip or of the spine and pelvis has on many occasions been treated as "rheumatism" before roentgenologic examination disclosed the true condition.

The joint complaints of the acromegalic patient may be clarified by the demonstration of the sella and skull changes, namely, enlargement of the sella, with or without atrophy, general enlargement with sclerotic changes of the skull, facial bones, lower jaw and the increased size of the extremities, particularly hands and feet.

The joint symptoms of the hyperparathyroid case, with collapse at times of some of the vertebral bodies, become clear when the generalized bony rarefactive changes and bone cysts are found. The mottled rarefaction of the skull and of the facial bones and the demonstration of urinary calculi may be the first clue leading to the demonstration of the characteristic chemical findings of hyperparathyroidism.

In large tumor clinics it is not at all uncommon to find cases which had been treated for months for a supposed arthritis

which on roentgenologic examination show the characteristic evidence of a local neoplasm, benign or malignant, or the destructive changes of bone metastases.

# SEARCH FOR FOCI IN ATROPHIC (RHEUMATOID), HYPERTROPHIC (OSTEO-ARTHRITIC), AND MIXED FORMS OF ARTHRITIS

**Teeth.**—Roëntgenographic examination of the teeth and surrounding structures may reveal the following:

1. Localized marginal pericementitis around vital teeth, due to pocket formation under overhanging metal fillings, food débris accumulations, alveolar recession, and dental caries.
2. Generalized pyorrhea, with extensive recession and absorption of the alveolar margin and formation of pockets around vital teeth, which may discharge pus and extend completely around one or more teeth.
3. Hypercementosis of dental roots, due to marginal pericementitis, or to low-grade infection with chronic irritation of the pulp.
4. Unerupted or partially erupted teeth with decay and infected pocketing.
5. Malposed teeth with decay, alveolar septic pockets, or even fairly extensive destructive changes of the alveolar bone.
6. Either nonvital or devitalized teeth with pericemental thickening or early granulomatous apical changes.
7. Incomplete or imperfect filling of root canals with pericementitis or granuloma.
8. Drilled false root canals with pericementitis or abscess formation.
9. Extensive caries, usually under metal fillings, which has extended to the pulp chamber and probably has caused the death of the tooth.
10. Apical pericementitis, where very large metal fillings resulted in the death of the tooth pulp. In these cases one sees thickening of the pericementum at the apex, associated often with hypercementosis of the roots. The hypercementosis represents the response of the tooth to a chronic low-grade infectious process in the pulp.
11. Apical granuloma, a more advanced stage of apical pericementitis. In granuloma the pericementum becomes detached from the root apex.
12. Apical epithelial cyst (radicular cyst), which represents a still later stage of dental root infection, in which the central portion of the granulomatous mass becomes liquefied. One must bear in mind that granuloma and apical cysts may be separated from the antrum by an extremely thin plate of bone, or may point directly into the antral cavity where the bony floor is dehiscant and may be separated from the antral cavity only by antral mucosa. An infected dental cyst may break into and infect the maxillary sinus and possibly by continuity, the other nasal sinuses.
13. Chronic root abscess with destruction of the pericementum, possible partial absorption of dental roots and bone scar formation in the alveolar structure surrounding the root. Chronic root abscesses may invaginate and infect the maxillary sinuses.

14. Diffuse alveolar bone destruction, starting immediately around the infected nonvital tooth and extending well into the surrounding alveolar structure.
15. Root fragments with a walled-off infective process or with an apical epithelial cyst.
16. Root fragments pushed into the antrum during extraction. These are usually associated with a draining oral fistula and infection of the antrum.
17. Maxillary fistula into the oral cavity at the site of dental extraction. If infection of the antrum follows and is not properly managed, a draining fistula with infection of the antrum and socket may persist for years.
18. Infected root cyst, left in alveolus after dental extraction.
19. Infected socket partially or completely closed over by alveolar healing before thorough drainage of infected material had taken place.
20. Socket infection associated with a diffuse low-grade osteomyelitic process of the adjacent bone.

The possibilities of dental infection are indicated here in detail to show the great care with which dental roentgenograms must be studied for their proper evaluation. The writer has repeatedly observed cases in which clinicians were satisfied to rule out dental infection on the basis of improperly made roentgenograms on which, at best, only the very gross and obvious pathologic changes could have been visualized. Not infrequently clinicians err in requesting incomplete dental examinations, limited to the remaining teeth only. In such cases it is not unusual to overlook completely the presence of infected root fragments, cysts, septic pockets, antral fistulas or low-grade osteomyelitis of the alveolus.

It should be evident from the above discussion that radiologic examination of the teeth and alveoli merits extremely careful study, if dental and alveolar infection is to be ruled out on the basis of such study.

**Paranasal Sinuses.**—The paranasal sinuses are often disregarded as an etiologic factor in chronic arthritis because of lack of clinical history of sinus involvement. It must be remembered, however, that marked pathologic changes may occur in the sinus membranes and cavities, with but very slight or no local subjective symptoms.

The rule should be to examine the paranasal sinuses of every arthritic patient in whom a focus is suspected, regardless of lack of history of sinus involvement (Hurd,<sup>30</sup> 1933).

Rhinologic examination may fail entirely in disclosing existing sinus pathology. This is particularly true where the posterior groups of sinuses are involved.

Roentgen examination of the sinuses may fail to disclose disease if great care is not taken with the many technical details essential in the production of good roentgenograms. The permissible latitude of technical error in the quality of sinus roentgenograms is very slight. The diagnostic value of sinus roentgenograms may be lost completely through faulty technic. In complicated and postoperative cases, many views at different angles may be required for proper visualization of the various sinus cavities. Views with the head inclined to one side may be necessary for the demonstration of fluid levels in the maxillary sinuses. For study of the frontals and ethmoids the orthodox postero-anterior and lateral views may have to be supplemented by oblique views of each side. For better visualization of disease processes along the antral floors particularly where sinus disease originates from dental structures and alveoli, the usual antral views may have to be supplemented by views taken obliquely between the rami of the mandible or by exposures made from behind, centering the rays through the space between the mandible and cervical spine. In some cases additional postero-anterior views may be necessary, exposed at such angles that the occipital rim and petrous bones will not overshadow the antral floors. Study of the sphenoids requires views that must show the right and left sphenoids separately. It may be necessary at times to make additional exposures, projecting the sphenoids on films placed in the mouth or utilizing angles which will project the sphenoid roofs into the frontal sinus area.

In chronic cases, particularly in postoperative cases, the routine roentgenograms may not suffice and some views may have to be repeated with deliberate overpenetration of the skull structures, in order to bring out some detail obscured by chronic hyperplastic or fibrotic changes. At times all these views may have to be supplemented by study of roentgenograms made after injection of opaque materials into the sinuses.

Slight movement of the head during roentgenographic exposure may completely ruin diagnostic detail. Slight rotation of the head on its vertical axis may produce false shadows which may lead to erroneous interpretation. The use of roentgen rays which are slightly overpenetrating or underpenetrating for the particular texture and calcium content of the skull

under examination, may completely blot out informative detail on the roentgenograms. The use of developing chemicals which are old, or at a higher or lower temperature than normal may completely nullify the diagnostic value of the roentgenograms.

In sinus roentgenography it is essential to expose and develop each film or stereoscopic set of films as the roentgenologic examination proceeds so that errors of technic may be rectified immediately.

Stereoscopic views are exceedingly helpful, and in many cases indispensable. The proper evaluation of sinus roentgenograms requires, as a minimum, views taken in four different positions, a lateral view, two postero-anterior views at different angles for the ethmoids and antra, and a cephalocaudal view for demonstration of the sphenoids. In addition to these the other views above described are often very necessary for the study and proper interpretation of sinus roentgenograms.

There is another reason why the sinuses are often overlooked as an etiologic factor in chronic arthritis, and that is the failure to regard roentgen evidence of thickened and polypoid membrane as indicative of possible sinus infection. There is a common tendency to disregard all roentgenologic findings in the sinuses if free pus cannot be demonstrated. It must be remembered, however, that thickened and polypoid membrane may in itself harbor infection, or may cover up abscess pockets.

### LUNGS AND HEART

In the investigation of the lungs roentgenologic examination is limited largely to the demonstration of chronic empyema, abscess, diffuse pulmonary suppuration and bronchiectasis. Cardiac infections present very little definite roentgenologic evidence. Nevertheless, studies of the heart contours and action are of value to the clinician in determining the presence of infective cardiac lesions.

### GASTRO-INTESTINAL TRACT

In the gastro-intestinal tract study of the colon may yield information of great value. In the esophagus, stomach and duodenum, if symptoms referable to these organs are

present, roentgenologic study may reveal diffuse inflammatory changes or localized ulcerations which may be of etiologic significance.

In the colon several conditions must be looked for. The most important is evidence of colonic stasis. Examination of the colon by barium enema, without preparatory cleansing of the bowel is the method of choice for the demonstration of colonic stasis. The colon should be examined routinely in all cases of chronic arthritis, regardless of history of normal bowel habits. It is surprising how frequently evidence of stasis or of colonic infection can be found in patients whose history does not point to bowel disturbance. It is not at all unusual to find the entire colon packed with fecal masses even shortly after bowel evacuation. In some cases, one finds localized spasm and serration and occasionally even partial obstruction at the site of colonic diverticula in the sigmoid or descending portion of the colon, indicating the presence of infected diverticula. In other cases, one may find abnormal dilatations of the colon due to gas accumulation or fecal stasis or very marked redundancy with kinking or looping of the bowel segments. In some cases the evidence of bowel irritability, namely marked spasticity, is further strengthened by the finding of marked turgescence and increase in the arborization of the mucosal folds, indicating the probable presence of catarrhal colitis. Occasionally ulcerative colitis may be demonstrated in arthritis patients.

The roentgenologic demonstration of irritability, stasis or infection of the gastro-intestinal tract is of great value to the clinician. There is fairly general acceptance today of the theory that such factors are of etiologic importance in chronic arthritis and must be eliminated if possible for the successful management of the case.

#### APPENDIX

Chronic appendicitis is a condition which does not lend itself readily to roentgenologic investigation. The roentgenologist can visualize the appendix, in most instances, if the appendiceal lumen is not obliterated. He can demonstrate the mobility of the appendix or its retrocecal position or unduly long retention of the opaque medium. He can elicit localized

tenderness by pressure directly over the appendix. The clinician must then evaluate these findings in the light of his clinical findings and laboratory data.

### GALLBLADDER AND URINARY TRACT

The search for gallbladder and urinary tract infection lends itself readily to roentgenologic investigation. The demonstration of enlarged, thickened, calcified gallbladders, of gallbladder adhesions, of gallstones, of pathologic conditions of the gallbladder, mucosa and of the urinary tract by modern roentgenologic methods is a comparatively fruitful field for roentgenologic investigation.

### BONE INFECTION

Old osteomyelitic infections of the bony skeleton and chronic mastoid infections are readily demonstrable roentgenologically.

From the above enumeration of roentgen studies of the teeth, sinuses, heart and lungs, gastro-intestinal tract, urinary tract, gallbladder and skeletal structures, it is evident that the roentgenologist can be of considerable assistance to the clinician in the search for obscure foci in chronic arthritis.

### ROENTGEN RAY THERAPY OF CHRONIC ARTHRITIS

A number of favorable reports have appeared in the literature on the use of roentgen ray therapy in chronic arthritis.

Scott<sup>37</sup> advises small doses of low penetration, and uses rays of comparatively high penetration in his hip cases. He obtained good results in "infective" and hypertrophic arthritis, but not in the atrophic cases.

Kahlmeter<sup>38</sup> reports that x-ray radiation is valuable in both the atrophic (rheumatoid) and hypertrophic (osteo-arthritic) forms of arthritis. He uses small fractionated doses at two- to three-day intervals. Sixty per cent of the atrophic cases and 40 per cent of the hypertrophic cases were benefited by this form of treatment. His atrophic spondylitis cases, however, failed to respond. He thinks the beneficial effect is due to reduction of capsular swelling and diminution of joint exudate. The analgesic effect may become evident within two or three days or not until two or three weeks after commencement

of treatment. Improvement may last for months. Certain patients responded to this form of therapy in whom all other methods had failed.

Douthwaite<sup>39</sup> (1932) is less optimistic as to the value of "deep x-ray therapy" in hypertrophic arthritis (osteo-arthritis). He feels that anything in the nature of a lasting improvement occurs in the minority of patients. The relief of pain, however, justifies the trial. He warns, however, against overdosage with its danger of leukopenia.

Watt<sup>40</sup> (1933) obtained 40 per cent of cures and marked improvement in 194 cases of hypertrophic arthritis (osteo-arthritis). The joints treated were the knees, hands, shoulders, hips and lumbar vertebrae (remaining joints rarely). He used from 50 to 60 per cent of a skin erythema dose, spread over 2 to 4 sittings and repeated in from six to eight weeks, when necessary. In the hypertrophic type, radiation is the treatment of choice and should be given early. In cases of long standing with disappearance of cartilage, deformity and bony overgrowth, the most one can hope for is relief of pain and some lessening of disability.

Hernaman-Johnson<sup>41</sup> (1931) thinks that x-ray radiation is least effective in atrophic (rheumatoid) arthritis. He obtained the most striking results in hypertrophic arthritis (osteo-arthritis). He believes the effect is due to the analgesic effect of the treatment, to reduction of joint congestion and to absorption of pathologic fibrous tissue.

Fried<sup>42</sup> (1934) states that roentgen treatment has at least two very desirable effects, namely, a rapid analgesic result and a decrease of swelling. These effects are similar in acute, sub-acute or the chronic stages in the infective, rheumatic or deforming types of arthritis.

Langer<sup>43</sup> (1933) claims that the majority of patients are benefited but that the results may not be apparent in some cases for several months.

#### SUMMARY

1. The chronic arthritides can be divided clinically into 9 main groups.
2. Roentgen classification of chronic arthritis on an etiologic basis is subject to many errors.

3. Roentgenologists today are generally of the opinion that the chronic arthritides of specific infectious origin do not present sufficient pathognomonic roentgen evidence to indicate the etiologic factor in each type. The roentgen changes may be of the atrophic, hypertrophic or mixed variety depending on the duration of the disease, the age of the patient and individual response of the patient to his infection.

4. Similarly the joint changes of the neuropathic arthritides and of those caused by faulty endocrine, metabolic or chemical processes and trauma are not sufficiently pathognomonic for an etiologic roentgen diagnosis.

5. In typical cases the roentgen appearance is sufficiently characteristic for a tentative roentgenologic diagnosis of atrophy (rheumatoid) or hypertrophic arthritis (osteo-arthritis). In many instances, however, the roentgenologist may find great difficulty in differentiating between these two forms of chronic arthritis. Roentgen evidence of both types may be present in the same patient and even in the same joint. Either type may predominate and largely mask the other. The final diagnosis should be made after consultation with the clinician and the correlation of all known facts.

6. The roentgenologist can be of considerable aid to the clinician in the discovery of obscure foci.

7. Roentgen demonstration of foci is dependent often on meticulous attention to numerous technical details of roentgenography.

8. Roentgen therapy of certain types of chronic arthritides may be of considerable benefit.

## CLINIC OF DR. MARTIN HENRY DAWSON

THE EDWARD DANIELS FAULKNER ARTHRITIS CLINIC, PRES-  
BYTERIAN HOSPITAL

---

### THE RÔLE OF THE STREPTOCOCCUS IN CHRONIC ARTHRITIS<sup>1</sup>

THE subject originally assigned for this clinic was "The Rôle of the Streptococcus in Chronic Arthritis." This vague title is no longer acceptable, for chronic arthritis cannot be regarded as a single disease entity. It includes a multiplicity of clinical conditions, many of which have nothing to do with infection in any way: for example, gout, trauma and neurotrophic disturbances. So, also, there are many varieties of chronic arthritis associated with specific infections, such as tuberculosis, gonorrhea, lymphogranuloma inguinale and many others. It is obvious that streptococcal infection plays no rôle in the pathogenesis of such conditions.

There remain, however, two great groups of chronic arthritis in which the rôle played by streptococcal infection has been debated for many years. These two varieties are variously designated by the following terms:

1. Osteo-arthritis, hypertrophic or degenerative arthritis.
2. Rheumatoid, atrophic or chronic infectious arthritis.

It is now generally accepted that these two forms constitute separate and distinct disease entities. Furthermore, it is being increasingly recognized that osteo-arthritis or hypertrophic arthritis is an age-period, degenerative disease and that infection plays no rôle in its pathogenesis. The precise cause of this form of arthritis is not known, but it is believed that constitutional tissue inferiority and trauma are important etiologic factors.

<sup>1</sup>From the Department of Medicine, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital.

Thus, there remains to be considered only one group, rheumatoid, atrophic or chronic infectious arthritis. Since the early days of bacteriology, this form of arthritis has generally been associated with some form of infection and much emphasis has been placed on the rôle played by streptococcal infection.

Rheumatoid arthritis is a systemic disease of unknown etiology, characterized by a chronic and progressive involvement of the articular structures. Although the disease picture is classical in its typical form, it may present the widest variations in individual cases. In spite of its protean manifestations, however, it exhibits certain clinical characteristics which justify the belief that it constitutes a single clinical entity. There now seems no justification for a separation of cases into such categories as "infectious" and "atrophic." Furthermore, several clinical entities heretofore regarded as separate diseases are now believed to be varieties of rheumatoid arthritis. Among these are rheumatoid spondylitis (Marie-Strümpell), Still's disease and psoriasis arthropathica. Such conditions are included in the present discussion.

Before proceeding to a detailed discussion of the evidence for and against streptococcal infection in rheumatoid arthritis, it is first necessary to consider some of the newer bacteriologic knowledge concerning the streptococci themselves. In general, streptococci are of three main varieties: the hemolytic, the green-producing or viridans and the indifferent. The hemolytic streptococci constitute by far the most important of these varieties and because of their overwhelming importance they have become the subject of intensive research by many investigators. Lancefield has shown that distinct groups exist within the hemolytic variety itself and that practically all strains which are pathogenic for man belong in Group A. Strains belonging to the other groups are frequently found as harmless saprophytes in man, but only in occasional instances are they responsible for clinical infection. For example, one of the natural habitats of Group D strains is the gastro-intestinal tract, but there is no evidence that these strains are ever pathogenic. Hare has shown that only about one third of the strains of hemolytic streptococci found in the upper respiratory tract of normal human beings belong to Group A. The remaining strains belong to groups which are essentially non-

pathogenic. These findings are of the utmost significance in the consideration of any disease thought to be associated with streptococcal infection.

Another fact of great importance in the newer knowledge of hemolytic streptococci is that a large number of distinct types exist within each group. Griffith has demonstrated at least 24 separate serologic types within Group A alone and probably others exist. As a result of these findings, it is now possible to determine not only the group to which each individual strain belongs, but also the specific type within that group.

The green-producing and the indifferent streptococci are among the most ubiquitous of all bacteria. They are widely distributed in nature and in man, but only in occasional instances are they ever pathogenic. Except in conditions such as subacute bacterial endocarditis, their rôle is almost exclusively confined to that of secondary invaders.

#### IMMUNOLOGIC TESTS FOR STREPTOCOCCAL INFECTION

Because of the wide importance of streptococci, particularly those of the hemolytic variety, a large number of immunologic tests have been devised to determine the presence of streptococcal infection. The more important of these are the following:

(a) **Agglutination Reactions.**—It is a well-known fact that agglutination reactions with streptococci are attended by great technical difficulties. Even in diseases definitely known to be associated with streptococcal infection, such as scarlet fever and erysipelas, conclusive results are difficult to obtain. In diseases of more uncertain etiology the results must be clearly defined before they can be considered as significant.

(b) **Precipitin Reactions.**—A number of precipitin reactions have been devised for the study of hemolytic streptococci under experimental conditions. The tests can only be carried out by experienced investigators and even in their hands the reactions do not yield information of any clinical value.

(c) **Complement Fixation Reactions.**—Complement fixation reactions can be obtained in a number of streptococcal diseases, but the results tend to be nonspecific in character.

Some of this difficulty is due to the fact that the various antigens employed contain nonspecific fractions which are common to a variety of related organisms. In general it may be stated that up to the present time no complement fixation reaction has been devised which specifically establishes the presence of streptococcal infection.

(d) **Antistreptolysin.**—Todd has recently shown that the hemolysin of hemolytic streptococci is antigenic and that, following acute hemolytic streptococcal infections, there is a marked increase in the antistreptolysin titer of the patient's serum. This test is of value in determining the presence of recent, acute, hemolytic streptococcal infection, but it is of little or no assistance in demonstrating the presence of low-grade or chronic infection.

(e) **Antifibrinolysin.**—Tillett has shown that, following acute hemolytic streptococcal infection, the serum acquires antifibrinolytic properties. Like the antistreptolysin test this reaction is of value in demonstrating the presence of recent acute infection, but it is of no value in determining the presence of low-grade, chronic infection.

(f) **Skin Tests.**—Skin tests done with streptococcal vaccines and extracts have been widely used by many investigators in attempts to demonstrate the presence of streptococcal infection. For the most part this type of work has been uncritical and lacking in adequate controls. After a detailed study of the problem Short, Dienes and Bauer concluded that without using several subjects as controls skin tests are without significance. Even with such precautions these workers state that skin tests are of no value in selecting strains suitable for vaccine therapy. In all work of this nature it must be constantly kept in mind that the skin sensitivity of a patient does not *prove* the existence of any relationship between the disease and the material that produces the skin reaction. It may suggest that the particular individual is either infected with, or is a carrier of, the organism in question, but it does not establish the fact that the symptoms of the disease are in any way related to the degree of sensitivity present.

From the foregoing résumé it is apparent that present immunologic and serologic methods are inadequate to establish the presence or absence of streptococcal infection. Although a

large number of tests are available, in the aggregate they can only yield evidence which at best is suggestive in nature.

#### EVIDENCE FOR STREPTOCOCCAL INFECTION IN RHEUMATOID ARTHRITIS

(A) **Direct Bacteriologic Evidence.**—1. *Cultures from the Blood and Tissues.*—Since the earliest days of bacteriology innumerable investigators have claimed to have isolated various forms of bacteria from the blood and tissues of patients suffering from rheumatoid arthritis. Some form of streptococcus seems to have been most frequently encountered, but there has been the widest divergence in the type of streptococcus recovered. Many investigators have consistently obtained negative cultures while others have obtained a variety of organisms. The complete lack of agreement in the results would in itself seem sufficient reason for regarding the findings with grave suspicion. It must be concluded that up to the present time no convincing evidence has been brought forward that streptococci are actually present in either the blood or tissues of patients suffering from this disease.

2. *Cultures from So-called "Foci of Infection."*—The failure to demonstrate bacteria in the blood and tissues has led to a large amount of investigation on the bacteria found in so-called "foci of infection." Here again some form of streptococcus has been frequently encountered, but there has been the same wide diversity in the nature of the strains. In all such investigations it must constantly be kept in mind that streptococci are almost ubiquitous in their distribution and that the finding of such organisms in the upper respiratory tract, the gastro-intestinal tract and on the skin is entirely without significance. All tonsils harbor streptococci within their crypts and in a recent study at the Presbyterian Hospital it was shown that over 90 per cent of enucleated tonsils contained streptococci of the hemolytic variety. Mention has already been made of the fact that the gastro-intestinal tract is a natural habitat of one of the groups of hemolytic streptococci. From the studies reported to date it appears that streptococci are not found any more frequently in arthritic patients than in normal individuals or in patients suffering from other diseases.

3. *Reproduction of the Disease in Animals by the Injection of Streptococci.*—Loeffler in 1886 was one of the first to pro-

duce arthritis in animals by the injection of streptococci. Since his time a large number of investigators have repeated this work but no one has yet succeeded in reproducing the true disease, rheumatoid arthritis. It is a comparatively simple matter to produce a low-grade septic arthritis in rabbits by the injection of streptococci of low virulence, but the disease so produced differs in certain essential respects from the naturally occurring disease. There is no evidence whatever that strains of streptococci recovered from patients suffering from rheumatoid arthritis are more effective in causing arthritis in animals than strains obtained from other sources and an entirely similar form of arthritis can be produced by many bacteria other than streptococci. It must therefore be concluded that such experiments contribute little or no evidence in support of the streptococcal theory of the etiology of rheumatoid arthritis.

**(B) Indirect Evidence of Streptococcal Infection.**—1. *Clinical History of the Disease.*—This constitutes one of the most cogent arguments in support of the streptococcal theory. It is generally acknowledged that in a significant proportion of cases the disease appears to be initiated by streptococcal infection. In our experience a definite history of such infection can be obtained in from 20 to 25 per cent of cases and invariably the streptococcus is of the hemolytic variety. In a further 20 to 25 per cent of cases a more equivocal history can be obtained. On the other hand, a large number of cases are encountered in which absolutely no history or signs of such infection can be elicited. In such cases the possibility of latent infection must be considered, but at the present time no methods are available to determine the significance of infections of this nature. In general it may be stated that the evidence obtained from clinical histories, while suggestive, is far from conclusive in establishing the rôle played by streptococcal infection.

2. *Immunologic Tests.*—(a) *Agglutination Reactions.*—In recent years a large amount of work has been done on agglutination reactions in rheumatoid arthritis. It has been established that in the majority of cases the sera of patients agglutinate hemolytic streptococci belonging to Group A in significantly high dilutions. However, great care must be exercised in interpreting these reactions. In the first place, it is

well known that agglutination reactions with streptococci are technically difficult to perform and cannot be done as a routine procedure. Experience has shown that the *strength* of the reaction is of greater significance than the actual *titer*. In the second place, although the reactions are highly characteristic for Group A hemolytic streptococci, the possibility remains that they may be nonspecific in nature. Finally, it must be kept in mind that even if streptococcal infection is present it may play a rôle of secondary rather than of primary importance.

(b) *Precipitins*.—Precipitin reactions with fractions of hemolytic streptococci suggest the presence of infection with Group A hemolytic streptococci in some cases of rheumatoid arthritis. From the practical point of view the tests are of no value in routine examinations.

(c) *Complement Fixation Reactions*.—Among the chief exponents of complement fixation reactions in arthritis are Burbank and Hadjopoulos. However, these workers themselves state: "The test is not diagnostic for arthritis alone but is diagnostic of a wide group of acute and and chronic infections that give rise to antistreptococcic bodies in human serum." The results of Burbank and Hadjopoulos can be further criticized because of their use of raw or unheated serum in fixation tests. It has long been known that active sera frequently fix complement nonspecifically and their use has been generally abandoned by workers in this field.

(d) *Antistreptolysin and Antifibrinolysin*.—These reactions have been studied by a number of workers in rheumatoid arthritis with rather equivocal findings. In the majority of chronic cases the results are within normal limits, but in many early and acute cases definitely high values are obtained. The findings suggest that in certain cases the disease is initiated by hemolytic streptococcal infection, but there is no evidence that the activity or persistence of the process is associated with the continuance of such infection.

(e) *Skin Tests*.—From the comments already made on the futility of skin tests in determining the presence of streptococcal infections in general, it would be expected that such tests would have little or no value in rheumatoid arthritis. Such indeed is the case. The skin reactivity of arthritis patients has been investigated by many observers and the results appear to be quite without significance.

*Allergy.*—Because of the failure to demonstrate bacteria in the tissues, numerous investigators have had recourse to the theory of bacterial allergy in its various forms. A detailed discussion of the evidence for and against this concept is not possible within the limits of this clinic. However, it can be stated that at present allergy is little more than an hypothesis and a rather unsatisfactory one at that. Profound as is our ignorance concerning the etiology of rheumatoid arthritis, many observers prefer to admit that ignorance rather than to accept an unproved theory which may only lead to further false assumptions and conclusions. In particular the hypothesis of allergy has led to a number of therapeutic procedures designed to "desensitize" the joints and tissues. Experience tends to cast much doubt on the value of all such procedures and an increasing number of clinicians are abandoning their use.

#### SUMMARY

The evidence so far available does not permit the formulation of any final opinion concerning the rôle of streptococcal infection in rheumatoid arthritis. Such evidence as there is incriminates streptococci of the hemolytic variety. There is no evidence that viridans or indifferent streptococci are concerned in the pathogenesis of this disease.

## CLINIC OF DR. CLARENCE A. DUNN

### ROOSEVELT HOSPITAL AND HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### ORAL FOCI IN ARTHRITIS

ANY discussion of arthritis would be incomplete without the consideration of mouth infection. At one time no attention was given to mouth infection, and unquestionably many cases of arthritis were pronounced as incurable, and the patient doomed to many years of suffering, where the elimination of some focus in or around the teeth and jaws would have brought great benefit to the sufferer.

With the theory of focal infection came the period of the wholesale, and often entirely unnecessary, removal of all the teeth, with no apparent benefits in the systemic disease, and the unfortunate one was rendered a dental cripple for the rest of his life. Fortunately, with the advent of  $x$ -ray, this condition has largely been corrected, though an opinion should never be accepted upon the  $x$ -ray findings alone, for many times foci that do not show by  $x$ -ray can only be uncovered by careful clinical examination. At the present time the pendulum is swinging from the wholesale removal of teeth to a saner and more conservative viewpoint. Close cooperation between the dental and medical professions is to be desired to prevent irreparable damage being done to the patient from both a medical and dental standpoint.

Since the advent of the theory of focal infection has been proved, much has been written concerning the rôle of pulpless teeth in systemic disease, and no hard and fast rule can yet be stated concerning them. Before the use of the  $x$ -ray it was common practice to pass these teeth as healthy, but radiographic examination proved many of them to be a menace.

Obviously, all pulp should be removed. arthritic condition, that some other foci that it is only in indirect rôle, but any is a menace to the get removed. It is in those evidence of pathology retention becomes a pre majority of this class of after the elimination of official results, then the re indicated.

Pulpless teeth are by no for as a focus in the mouth with their attending infectio alveolar process, gingivitis, bridge work, and Vincent's i: foci as are pulpless teeth.

Any infection in the mouth of the body by direct absorpt. absorbed through the gastro-inte sity of proper treatment of oral c radiographic examination.

Impacted teeth should be ren crown has erupted through the alv made no provision for the attach crown of a tooth, so consequently, erupted, an ideal point of entrance fo produced. Cultures taken from pool partially erupted teeth invariably give

Pyorrhea must always be eliminat health can be given on the mouth. To produced by this condition are unque and pressure of the gums around them of pus. If the disease has progressed to alveolar process has been absorbed so r loosening of the teeth, has gained access of the roots of the multirooted teeth, or

proper treatment, then the only safe procedure is the removal of the affected teeth.

It is important that complete x-rays be taken of every mouth, regardless of how long the teeth may have been removed, for in a large percentage of edentulous mouths will be found root fragments or residual infection.

The removal of oral foci, while not a panacea in the treatment of arthritis, is certainly important, and in certain cases will be found to be the direct cause of the disease. If not the direct cause, the elimination of the oral foci is to be desired, for it will unquestionably improve the general health.

## CLINIC OF DR. PAUL H. BREUNING

### HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### THE TONSILS AS FOCI OF INFECTION IN ARTHRITIS

INFECTION within the tonsils and pharyngeal lymphoid tissue has long been recognized as associated with acute and chronic arthritic symptoms. In any given case there is likely to be considerable controversy among the attending clinicians as to whether the tonsils are acting as a focus of infection or as the source of toxic irritation to the joints. Recently an effort has been made to emphasize that they are only of etiologic importance in rheumatoid arthritis and that they are only coincidentally infected in cases of osteo-arthritis. On the other hand, many experienced clinicians feel that they may act as direct etiologic factors in both types of arthritis. These differences of opinion emphasize the fact that tonsillar clinical diagnosis has not yet been perfected.

The anatomy is well known to all, but the physiology is more vague. We are accepting the premise that the tonsils in health are a destroyer of local infection and a guardian against the entrance of this infection into the general system, especially during the period of the exanthematous fevers of childhood. This is probably the period which largely controls the rest of the life of the tonsils. The throat being the site of attack common to most all childhood contagions and infections, it is not surprising that by the age of puberty considerable damage may have been done to the cellular structures of the tonsils, with consequent hypertrophy and formation of scar tissue. If the tonsil has withstood these attacks upon it during this period and has been able to carry on its functions with efficiency, it probably will follow its natural course, gradually atrophying, until later in life it becomes so small and flat that the tonsillar fossa will appear practically empty.

Our problem is to determine what diagnostic signs are present that lead us to believe that the tonsil is acting as a focus of infection, and whether this toxic influence is affecting distant organs, such as the joints, in any given case of arthritis. These clinical signs are to be carried in mind during the examination of every case. Moreover a complete tabulation should be made of distinctive features in order that the examiner may have an exact picture of the tonsil as it appeared at the examination so that later the picture of the tonsil may be accurately recalled when checking up the present status of the patient.

The factors upon which conclusions are based and opinions made vary so greatly that absolute diagnosis can only be made in a moderate percentage of cases. But the conscientious correlation of these factors will enable one to give a very helpful opinion in a large percentage of cases, and in a definite, though perhaps small, percentage absolute answers instead of opinions can be given from the clinical signs and history.

The aim of this article is first to state for the general practitioner and the specialist in other branches of medicine, the principles of tonsillar diagnosis, and secondly to show that infected tonsils are found in the great majority of cases of rheumatoid arthritis. Thirdly we wish to emphasize that infected tonsils are also found in cases of osteo-arthritis and that even in these cases their removal is frequently followed by a satisfactory improvement in the patient's symptoms, provided all the other possible etiologic factors are also eliminated.

Quite significant is any difference noted in the appearance of the two tonsils. Since they are both influenced by the same physiologic conditions, a breakdown in normal function of one may be quickly demonstrated by comparing it with the other. Other features to be carefully recorded are:

1. Size.
2. Embedded or coverage by pillars.
3. Consistency, sclerotic and hard or soft and spongy.
4. Color, pale or congestively red.
5. Circumtonsillar flush, caused by congestion of mucous membrane of anterior pillar and soft palate; its depth of color and width are very significant as to the amount of irritation underneath
6. Determination of contents of crypts by pressure against anterior pillar behind the tonsil, with a blunt or a hard retractor, partially evulsing gland,

will usually express its contents where there are large deep clefts or crypts: if no acute inflammation is present, blowing air down into them through a cannula or straightened eustachian catheter may be used to force contents out, or suction through a wide-mouthed glass tube, fitted over the tonsil, will bring out its foreign contents.

7. Characteristics of substance expressed, chalky concretion, caseous, creamy, milky and if odoriferous, bacterial examinations of this material will help, especially with the repeated finding of a vicious hemolytic organism in the expressed substance from the gland.

8. The presence of an enlargement of the lymphatic glands of the neck, particularly under the angle of the jaw.

Upon the sum of these findings and the review of the history, such as a relation between acute throat flare-ups and distant systemic symptoms, you will have the material for judging the guilt of the tonsils and whether capital punishment is to be invoked.

We will classify the various infected tonsils under acute, subacute and chronically infected tonsils.

The acute infection picture is a familiar one. The tonsils are usually red or angry looking, and more or less swollen, and with or without exudate and minute abscesses in the tonsillar crypts. There is usually red congested mucous membrane throughout the throat, accompanied by general toxic symptoms. While this condition is present or subsiding, if joint symptoms commence or there is an acute exacerbation of a chronic arthritic condition, we have a logical link, with its sequence almost becoming obvious. If there is a previous history of this same sequence having occurred before, there can be little doubt as to at least one of the factors contributing to the joint derangement; and removal of the tonsils will bring gratifying results and help greatly to reduce the probability of slowly developing joint changes, which are most likely eventually to follow. Even though the condition clears up entirely in the joints, following the resolution of the throat lymphatic structures, the tonsils should be removed as a prophylactic measure. Where the above close sequence between the acute tonsillar infection and the appearance of arthritic symptoms has been present in the history, the writer has noticed a more frequent, temporarily acute exacerbation of arthritic symptoms arising following the subsequent tonsillec-

tomy, than where no such sequence was noted in the previous history.

Our greatest difficulty arises in expressing our opinion where the subacute and chronic tonsils are in question, as these two conditions blend one into the other, and the diagnostic signs in relation to arthritis apply to each. They will be treated here together.

The type of tonsil, simulating most of the subacute infected gland but in reality a chronic infection, is the very large, dull red, spongy tonsil, from which little if any secretion can be expressed. The band of congestion, along the anterior pillars and the soft palate, is wide and deep in color, if other signs of acute throat inflammation are lacking. The tonsils are protruding and tend toward being obstructive. There is usually some enlargement of the lymphatics at the angle of the jaw or of the cervical chain, but as they are usually found in fat, thick-necked type of persons, it may be difficult to feel these glandular enlargements. The patient having this type of tonsil is usually surprised to hear his tonsils are bad, and will state he has never had any throat trouble in his life. This type of tonsil is seen very frequently in clinics where there are many southern Europeans. Where these conditions are found, the tonsils can practically always be considered as an infective focus and will require removal.

A difficult tonsil to judge is the small, hard, pale gland, which appears normal at first. The size may not be due to atrophy but to a fibrosis, resulting from long-standing, inflammatory irritation, and be largely covered by the anterior pillar, due to adhesions. The outer layer is sclerotic and together with the pillars drawn over tightly; the glandular tissue becomes enclosed. If there is infection within, which there usually will be with these conditions present, some of the before-mentioned clinical signs will be present. The most frequent and indicating sign will be a heavy band of circumtonsillar congestion and will indicate that there is marked irritation within. Because of the necessity for absorption of the resulting products from such a deeply placed infection, there will be a prominence of the gland at the angle of the jaw or of the cervical lymphatic chain, and usually an increased sensitiveness of the tonsil or pressure behind it. This type of small

tonsil, looking quite innocent, may be quite vicious in its absorptive effects and might even contain localized pockets of pus in its bed, which can only be demonstrated at the time of operation. Where tonsils of this innocent appearance are encountered, your course will be to proceed first with an exhaustive search in the other medical departments for a focus of absorption and postpone the removal of the tonsils until the other possible sources have been found negative, but continue to consider the tonsils with suspicion and potentially very vicious.

The more frequent type of chronically infected tonsil met with is the gland of moderate size, dusky red with fairly large clefts and crypts in the upper third. There will always be a pronounced band of congestion along the pillars and palate. Pressure will express a pastelike or a milky secretion; the latter we consider the most dangerous type of secretion expressed. The tonsils will usually be sensitive and the gagging reflexes quite active. These are always infected tonsils, producing systemic absorption. They should be removed whether they are causing distant symptoms or not, as the patient's health will continue to be in jeopardy as long as they remain.

Secondary tonsils, or tonsillar stumps, for which there is seldom any excuse, are one of the most vicious types of all in producing distant absorptive symptoms. Its abundance of scar tissue, organized during the process of healing after the primary partial tonsillectomy, seals the surface tightly. The superficial vascular constriction makes the remnant appear pale and innocent, but the absorption that may result is far greater than the amount of gland left would indicate. A small piece of the gland, entirely closed in, can alone keep a generalized arthritis progressing. This was shown in a number of reported cases of Dr. Snyder's with the late Dr. King some years ago. All tonsillar tabs and stumps should be eradicated, particularly if embedded. Embarrassing as it may occasionally be to tell the patient, the fact remains that tonsils cleanly removed in patients over six years old seldom recur.

Little need be said about the adenoids and other pharyngeal lymphatics, except that they should be examined with the same thoroughness and when infected, removed as completely as

tomy, than where no such sequence was noted in the previous history.

Our greatest difficulty arises in expressing our opinion where the subacute and chronic tonsils are in question, as these two conditions blend one into the other, and the diagnostic signs in relation to arthritis apply to each. They will be treated here together.

The type of tonsil, simulating most of the subacute infected gland but in reality a chronic infection, is the very large, dull red, spongy tonsil, from which little if any secretion can be expressed. The band of congestion, along the anterior pillars and the soft palate, is wide and deep in color, if other signs of acute throat inflammation are lacking. The tonsils are protruding and tend toward being obstructive. There is usually some enlargement of the lymphatics at the angle of the jaw or of the cervical chain, but as they are usually found in fat, thick-necked type of persons, it may be difficult to feel these glandular enlargements. The patient having this type of tonsil is usually surprised to hear his tonsils are bad, and will state he has never had any throat trouble in his life. Secondary tonsils, or tonsillar stumps, for which there is seldom any excuse, are one of the most vicious types of all in producing distant absorptive symptoms. Its abundance of scar tissue, organized during the process of healing after the primary partial tonsillectomy, seals the surface tightly. The superficial vascular constriction makes the remnant appear pale and innocent, but the absorption that may result is far greater than the amount of gland left would indicate. A small piece of the gland, entirely closed in, can alone keep a generalized arthritis progressing. This was shown in a number of reported cases of Dr. Snyder's with the late Dr. King some years ago. All tonsillar tabs and stumps should be eradicated, particularly if embedded. Embarrassing as it may occasionally be to tell the patient, the fact remains that tonsils cleanly removed in patients over six years old seldom recur.

Little need be said about the adenoids and other pharyngeal lymphatics, except that they should be examined with the same thoroughness and when infected, removed as completely as

possible. It is well to remember that infected adenoid tissue is more likely to recur after removal than infected tonsils.

Histologic examination helps to confirm a correct opinion, but it is a little late in helping the preoperative diagnosis. When enough such examinations have been tabulated, they will help standardize the occurrence of infection in these different types of tonsils.

Next to establishing the guilt of the tonsil, the most important step is the correction of its vicious influence. Local treatment of chronically infected tonsils by antiseptics, with the idea of effecting its systemic absorption, is a waste of time. x-Ray therapy will shrink the tonsil but does not eliminate its contained infection. In fact positive bacterial cultures can be taken immediately following the treatment. Electrical coagulation is not efficient enough in cases of chronic arthritis where every vestige of tonsillar tissue must be removed, as the mucous membrane may grow over the small pieces of gland tissue and bury them, leaving a smooth, clean-looking fossa. The writer has seen abscess formations develop later from pieces of tonsillar tissue buried in this manner. If the tonsil is causing the arthritis, you must know it is absolutely all cleanly removed.

The most certain means of thorough eradication is the clean enucleation of the gland, removal of the plica triangularis and any lingual lymphatic tissue projecting up into the base of the tonsillar fossa.

There are very few contraindications to doing a tonsillectomy when the clinical picture clearly points to them as interfering with the health of the patient. Any other organic disturbances should be, as nearly as possible, corrected, and we know from practical clinical experience that infected tonsils are the most frequent foci of infection in cases of rheumatoid arthritis. Depending upon conditions elsewhere in the body, a choice between local and general anesthesia will make the procedure comparatively safe.

Conditions such as cardiac disease, even though some degree of decompensation is present, surprise one with the ease in which they withstand the operation. Hemorrhages now and then complicate the situation but tying all bleeding points will eliminate most postoperative hemorrhages. Secondary hemorrhages are always possible, due to infection from the mouth.

Dr. William Turnley reports 76,000 cases without a hemorrhage death. Age is not a contraindication, unless the patient is extremely infirm, as patients over fifty are often less upset by the procedure than younger people. In the past ten years at the Hospital for Ruptured and Crippled, we have done over 1800 tonsillectomies, ranging in age from one year to seventy-eight years, without a single death from any cause. If the clinical signs clearly point to the tonsils, do not hesitate to remove them. If only a uniform set of descriptive signs would be used by all investigators in tabulating their results, so that others' results could be compared, progress would be made much easier and faster for the general physician, as well as for the specialist, in finding out which signs are the most indicative and the type of tonsil most vicious in producing systemic inflammatory and toxic disturbances.

The tonsils should not be blamed for any ills without logical clinical reasons being present. The abdominal surgeon does not remove the gallbladder just because there is something wrong in the abdomen. If the tonsil is diseased, clinical signs will be found, if looked for; the history is generally significant, if thoroughly investigated, and a relationship to the distant inflammatory condition found. There has been in the past a pernicious tendency to blame the tonsils for joint and systemic disorders, whether or not clinical signs were present which pointed to it as the culprit. Remember that our knowledge of the underlying physiologic and chemical reactions of the body is still very limited, and the tonsils should not be used as a substitute just because no other cause can be found.

### CONCLUSIONS

1. Infected tonsils are probably the most frequent and important foci of infection in cases of rheumatoid arthritis.
2. They act also as frequent foci of infection in osteoarthritis. However, as these patients are generally over forty years of age, when resistance to infection is relatively high, the benefit resulting from removal of tonsils in this group of patients is relatively less, though definite, according to the age of the patient. Age in itself is not a contraindication for tonsillectomy.

3. Many innocent appearing and symptomless tonsils harbor latent infection in the crypts. In these cases it is necessary to apply pressure behind or externally to the tonsil in order to express infected material, generally from the upper pole.

4. Tonsillar stumps and remnants should be viewed with suspicion. It is not possible to be absolutely sure that all tonsillar tissue has been removed by electrocoagulation.

## CLINIC OF DR. LEE M. HURD

NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL

---

### THE NASAL ACCESSORY SINUSES AS FOCI OF INFECTION IN ARTHRITIS

THE writer believes that acute or chronic sinus infection either aggravates or is the cause of many cases of chronic arthritis because he has observed many cases of arthritis in his own practice that were benefited by the eradication of sinus infection.

Snyder, Fineman and Traeger,<sup>1</sup> in a careful study of this question, show that in a series of nearly 400 consecutive cases of arthritis seen in office practice, there was some x-ray evidence of sinus infection in 68 per cent, the majority of which gave no history or subjective symptoms of sinus trouble at the time of examination. Of those who had subsequent sinus treatment, either medical or surgical, 80 per cent showed various degrees of improvement in their arthritic symptoms, which seems to prove that sinus infection is a definite cause of arthritis. The writer personally observed and treated the majority of these cases and can substantiate the statement that when the sinus infection was relieved either by conservative methods or surgery, the patient was greatly benefited, some becoming entirely free of arthritic symptoms.<sup>2</sup>

Sinus infection occurs most frequently in the cases of rheumatoid arthritis, occasionally in the mixed type, and somewhat less frequently in the osteo-arthritis group.

In the rheumatoid arthritis group where sinus infections were present (usually of the silent type), patients frequently failed to show improvement until the sinus condition was cleared up, even though every other condition that might have caused the arthritis had been excluded or corrected. Ten of

the cases on whom the writer operated have been greatly improved or freed of sinusitis and arthritis for a period of from eight to eleven years. Sixty per cent of these were classified as rheumatoid arthritis, 20 per cent as mixed type of arthritis, and 20 per cent as osteo-arthritis.

The ethmoids were always involved, most frequently in association with the maxillaries, but occasionally they were involved with the frontals or sphenoids. In some cases all the sinuses were simultaneously involved. Ethmoiditis in these cases was usually of the hyperplastic type, that is, showing evidence of thickening of the mucosa and sclerotic changes in the bony walls. Only a little mucopus was commonly found in the ethmoids. Pus was more in evidence in the maxillary sinuses. The bacteria, when cultured, were usually so mixed in type that it had no significance.

The tonsils are commonly supposed to be foci of infection of the first rank, but in this series more than two thirds of the cases had previously had tonsillectomies without benefit to the arthritis. This would lead one to believe that the tonsils had been removed because they were the more apparent and easily accessible foci, while the sinuses were overlooked to the detriment of the patient.

The majority of these patients had no subjective symptoms of sinus disease, and were not aware that they had it. About one third of the cases had purulent nasal discharge, which is often designated as a postnasal drip. Sinus headaches were rare. In view of these facts, every sinus examination of a patient suffering from arthritis should be thorough and complete. The procedure is as follows:

Examine the nose anteriorly and posteriorly to note the condition of the mucosa and the presence of secretion. Then shrink the nasal mucous membrane and transilluminate the antra and frontal sinuses. If the transillumination suggests chronic frontal or antral involvement, give particular attention to shrinkage about their orifices and again note the character of the mucosa and secretion.

The middle turbinates, with the mucosa of the middle meatus, tell much about what may be going on in the ethmoids, frontals and antra. The writer does not believe it is possible, if there is involvement of the ethmoids or frontals, to find a

middle turbinate whose membrane is clear, smooth, glistening or normal in color. The middle turbinate because it is part of the ethmoidal labyrinth, takes on the same mucosal change as the ethmoidal cells. One of the first changes noted when the ethmoids become involved is change in character of the mucosa of the middle turbinates, especially along their lower border and at the anterior and posterior ends.

Transillumination is a great aid in detecting sinus involvement in the antra and frontal sinuses, and should always be used as a routine procedure. Too much value should not be placed upon it, however, because an involved sinus may transilluminate clearly, or the reverse is also true. A sinus may transilluminate darkly, where the active process has long since subsided, if the bony walls are thick or have become thickened from a previous operation. Transillumination is of no value for the ethmoids and the sphenoids, because of their inaccessibility. For diagnosis of pathologic conditions in these sinuses we must depend upon x-ray findings and the reports of the rhinologists.

Roentgenographic studies of the paranasal sinuses should be made in all cases of arthritis, regardless of whether or not the patient has nasal symptoms. It is important that they should be well made. Poor films are worthless. They should be made in 4 stereoscopic pairs, at proper angles. These are of great value in elaborating the clinical information, but here again previous inflammations and operations may have produced fibrous thickening of the tissue which will obstruct the rays, and produce a picture similar to that of a sinus full of pus. At times, however, even good films will not always confirm the clinical findings. Finally, the x-ray films should always be interpreted in the light of the clinical evidence.

Some mild cases of sinusitis will respond to conservative treatment, and in others surgery is indicated. The treatment consists in shrinking the membranes, applying a mild silver protein solution, and douching. Vaccines may also be used which sometimes benefit the patient but many times do not. In antral infections daily douching is indicated, and if there is improvement in the character and quantity of the secretion, this treatment may clear up the infection, and operation will not be required. About 75 per cent of the cases may be

douched through the natural orifice; in the remaining 25 per cent needle puncture will be necessary.

Surgery must be resorted to if the following conditions are present:

1. Polypoid degeneration of the ethmoidal mucosa with an associated osteitis of the cell walls. This can be definitely determined by inspection and in the stereoscopic films.

2. Greatly thickened mucosa in the frontals or antra. Drainage at least should be established, but it is better to remove the infected mucosa.

3. Badly infected ethmoids that have not improved following the use of conservative methods of treatment.

The sinuses should be strongly suspected if the patient has a slight elevation of temperature; if there is profuse purulent discharge in the back of the throat; or if there are headaches related to the sinuses. When the above symptoms are present, conservative treatment is a waste of time, and only surgery will afford relief and effect a cure.

In order to be successful, an operation on the sinuses must be thorough and complete. A submucous resection of the nasal septum must be done whenever indicated, as this gives a much better view of the ethmoidal labyrinth. If the ethmoids are involved the exenteration must be complete, for if part of the cells remain the patient will be no better off than before. This is true of all the sinuses; all infected, degenerated membrane must be removed.

It is important to remember, however, that there may be an underlying cause of the sinus infection such as: (*a*) deficiency in vitamins, (*b*) allergia, or (*c*) endocrine imbalance. It is obvious, therefore, that if a cure is to be effected, the cause or causes must be determined and corrected.

A cold may precipitate a slight flare-up in a sinus but if the operation has been successfully performed and adequate drainage has been established, the infection will promptly clear up with a few treatments, and there should be no ill effect on the arthritis.

It is generally believed that a winter spent in a dry climate such as in Arizona, will cure sinus disease, but this is not always the case. A dry, mild climate frequently reduces the number and severity of upper respiratory infections, but

unless the residence is permanent, no lasting benefit will be derived.

"Once a sinus case, always a sinus case" is a pretty slogan which is prattled by the laity, and, the writer is sorry to say, by some doctors who are apparently just as ignorant of the situation as the layman. The fact is that the majority of sinus infections can be permanently cured if the sinuses are intelligently and skilfully treated.

**Summary.**—1. The nasal accessory sinuses are important factors in chronic arthritis.

2. Involvement of the sinuses often gives few or no symptoms.

3. In most of the cases in this report there was no frank pus and few headaches. These cases might be termed "silent sinusitis."

4. In refractory cases the best results were obtained by surgery.

## CLINIC OF DR. DAVID N. BARROWS

### HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### THE FEMALE PELVIS AS A FOCUS IN ARTHRITIS

THE numerical importance of the female pelvis as a focus of infection varies directly with each group of patients studied. This is dependent directly on the frequency of past and present gonorrhea in each particular group, with its accompanying arthritides explaining this variation.

Assuming for the moment that all cases with active neisserian inflammations are eliminated, there will be found a definite proportion, probably always less than 10 per cent of female arthritis, where pelvic foci can definitely be proved to be an important cause of arthritic phenomena.

As far back as 1910, and again in 1913, the late Frank Billings drew attention to the necessity of cleaning up the cervix uteri where the focal point of infection was obscure. In a series of 60 female arthritics studied by Munro and reported in 1909, 60 per cent were found to have distinctly purulent vaginal discharges and K. S. Clark in 1908 and Bannatyne in 1904 regarded the uterus, ovaries and pelvic mucosae as potent sources of focal toxins.

Sturmdorf of this city, in 1916, in support of his enucleation operation for the cervix uteri, named the cervix "tonsil of the uterus" and, shortly after this, Friedlander drew attention to its activities as a focal point of infection. In 1923, R. L. Dickinson gave a simple anatomic explanation of its activities; *i. e.*, that its lymphatics are open spaces around the gland cells of the mucosa, opening into lymphatic channels which pass, in part, directly to the parametrium. Others connect with the lymphatics in the body of the uterus, determining parametritis and infections of the fallopian tubes and ovaries. When a

cervix becomes brawny and indurated it is easy to visualize its potentialities, but Dickinson gives us a clearer idea of why the simpler erosions, ulcers and cysts may prove to be active foci.

About twelve years ago, Moench reported experimentally from the Mayo Clinic, drawing attention to the pelvic focus and its potentialities. She cultured the deeper layer of chronically inflamed cervixes, and produced definite arthritis in inoculated animals. Some question has been raised as to the specificity of this experiment, but it was subsequently confirmed by the work of Barrett, Lash and Pillot.

Robinson in the *British Journal of Physical Medicine* as recently as 1935, as reported in the 1936 *Rheumatism Review* prepared by a committee at the request of the American Association for the Study and Control of Rheumatic Diseases, feels that infection of the uterine cervix and prostate gland is in most cases responsible for arthritis. He noted consistent improvement only when these (and other infected foci) were treated. "There is," he says, "no remedy for it except (long-wave) diathermy, *i. e.*, a wave length of 100 to 400 meters with a current frequency of  $\frac{3}{4}$  to 3 million cycles per second." This he specifies should be "given intrapelvically by special electrodes."

We all appreciate that diathermy, since its first use in medicine, has been recognized as of great value in pelvic infections and this conclusion by Robinson is in exact conformity with the experience of the early English workers, mentioned above.

It has been my privilege to make gynecologic examinations on about 4000 arthritis patients during the past ten years in one of our larger arthritis clinics, at the New York Hospital for Ruptured and Crippled. After all other contributing foci have been eliminated to the best of our ability, cases where the pelvic focus appears largely responsible seem to run between 6 and 8 per cent. In this particular group, there are very few gonorrheal cases, probably less than in the average general practice in this city. The large majority of the active pelvic foci demonstrated are: infected or eroded cervixes, fibroids of the uterus, postabortal or instrumental infections, with an occasional salpingitis and parametritis.

On our gynecologic service at Bellevue Hospital no cases of arthritis are accepted unless diagnosed as gonorrheal. Some of them turn out later to be mixed infection, but this may be a transition from one to another due to subsequent invasion of other bacteria.

As regards treatment, *i. e.*, removal of the focus, the gonorrheal, and the nongonorrheal or mixed infection form two very distinct groups.

Taking up the mixed-infection group first, we find that many of the cervical foci can be relieved by local and office treatments. One very valuable adjunct we find to be the Elliott apparatus, which raises the local pelvic temperature by insertion of a distensible vaginal rubber bag of special design through which water heated to fixed temperature is pumped for periods of one to five hours. A similar bag can be used in the rectum, *e. g.*, in prostatic cases.

We have found that many obstinate cases of pelvic inflammatory disease will respond beautifully to this medium, and we use it more extensively than pelvic diathermy.

At Bellevue Hospital it has proved very valuable in our latest modification of the hyperthermia treatment in use for neisserian infections. We have been able to obtain better results by using the Elliott apparatus to raise the local pelvic temperature to 109° or 111° F. by pumping in water at 120° F., with a general body temperature elevation of 105° to 106° F., using a heating box, than we could achieve by elevating the general body temperature to 106.8° or 107° F. Also, this combined method has proved much safer in our hands and less distressing to the patients. Local burns in the vagina have been of no moment in over five years' constant use of a half dozen machines, going practically twelve hours a day, which is quite different from our experience with local pelvic heat by radiotherm.

This modification has apparently eliminated the grave dangers of prolonged hyperthermia at effective heat levels.

If they do not respond to these simple measures, then the problem is larger. In cases where the mixed infection has passed or lies beyond the confines of the cervix, Snyder believes that it becomes deeply entrenched in the parametrium. This has proved to be the case in many of our infections follow-

ing intra-uterine instrumentation and induced abortion and although the pathology appears entirely confined to the lower uterine segment, an extensive removal of tissue by Sturmdorf enucleation up to the internal os uteri has been followed by complete disappointment in a number of cases in my hands and those of others in our clinic. For these, for fibroids of the fundus uteri, and for salpingitides of this group, removal of the uterus as a whole, by complete rather than supravaginal hysterectomy, is the most successful treatment at our hands. C. H. Mayo in 1927 apparently came to much the same conclusion, for, in speaking of the removal of the fundus uteri for focal infection, he advised the subsequent removal of the cervix if only temporary or no relief is obtained by the first procedure.

A few brief case reports where we have been able to have good follow-up data may serve well to illustrate these points.

**Case I.**—M. D., aged thirty-one, private secretary. Arthritis following criminal abortion, with badly torn and brawny, infected hypertrophied cervix. Complete invalidism from involvement of many joints of hands and legs. Gonococcus complement fixation negative. Cervical and urethral smears negative for gonococci. All other potential foci negative.

High Sturmdorf removal of cervix. No other pathology palpable.

Result: 100 per cent failure. No improvement observed in three years.

**Case II.**—M. A., aged fifty-two, housewife, infected cervix. Para 2. No history of postpartum infection. All other potential foci eliminated. Menses regular and normal amount. Crippling of hands, knees and hips. Slight improvement following office treatment.

High Sturmdorf removal of cervix. No other demonstrable pelvic pathology.

Result: 100 per cent failure. No improvement for four years.

**Case III.**—M. L., aged forty-two, uterus duplex unicornis. Fibromyomata of both fundi. Multiple joints with marked deformity. Other foci eliminated previously.

Relief after two months. Excellent result for eleven years following complete hysterectomy with bilateral salpingo-oophorectomy.

**Case IV.**—M. S., aged forty, child's nurse. Early abortion by nonsterile instrument. Other foci eliminated. Bedridden for two years. Marked deformity of the hands and feet.

Operation: complete hysterectomy with bilateral salpingo-oophorectomy

Relief after one month. Able to work for past ten years

Case V.—M. B., aged thirty-seven, ex-chorus girl.

Other foci cleaned up. Multiple points with active arthritis. History of at least 17 criminal abortions. Bilateral large hydrosalpinx.

Operation: complete hysterectomy with bilateral salpingo-oophorectomy.

Result: excellent at least five years.

Case VI.—H. H., aged forty-one, Swedish housewife. Multiple joints and deformity and peri arthritis. Multiple fibroids of the uterus. Other foci clear. Cervix small and clean. Probably not infected.

Supravaginal hysterectomy with bilateral salpingo-oophorectomy.

Result: excellent; followed for two years, then lost.

Due to difficulty of anesthesia complete hysterectomy not attempted, planning to remove cervix later.

This result we consider quite fortunate as we have seen 10 or more cases where supravaginal hysterectomy alone proved of no value.

Case VII.—E. C., aged forty-five, chambermaid in hotel.

Supravaginal hysterectomy fifteen years before for gonorrheal salpingitis. Reinfected two months previously with severe arthritis knee and hand. Smears of cervix and urethra were negative for gonorrhea on our wards. Showed mixed organisms.

Operative removal of cervix from below revealed pocket containing 5 to 7 cc. thick pus, culture negative.

Probably a "pyometra" of the upper end of cervical stump.

Result: slow but excellent for at least four years.

Knee shows limitation of motion but patient cannot take time off for orthopedic care. No arthritis since leaving hospital.

We have also treated locally 6 cases of definite recurrent adnexal complications where the arthritis improved on repeated occasions while under gynecologic treatment, one over a period of six years. None of these cases has come to operation, as they can be comfortably relieved of each attack by a few clinic visits.

All other potential foci in these cases have been pronounced negative. It must be remembered that the improvement of their general health resulting from the pelvic treatments may explain these results.

The report of the committee previously mentioned emphasized the difficulty of the diagnosis of gonorrheal arthritis. In reviewing a carefully recorded series of 85 cases reported by Kufu, Myers and Gwynn, attention was called to several points which they consider worthy of reemphasis, some of which are as follows:

"An initial polyarthralgia may resolve into a more stubborn monarthritis. . . .

"Knees, ankles, wrists, metacarpophalangeal joints and shoulders are most frequently affected. . . .

"Involvement of sternoclavicular joint is unusual." (Two out of 85; in our series of a similar number, 4.)

"Spurs of os calcis are rare" (7 in 85 cases) "confirming Von Lackum's contention (1930) that gonorrheal spurs is a misnomer."

They draw attention to the opinion of the Neisserian Medical Society of Massachusetts that an honest history and special knowledge of the relative significance of clinical and laboratory data are important.

The report published April 10, 1937, by Warren, Hinton and Bauer, working under a grant of the Rockefeller Foundation, from the medical clinic of the Massachusetts General Hospital, Harvard Medical School and Wassermann Laboratory of the Department of Health of the Commonwealth of Massachusetts emphasizes the value of the gonococcus fixation test when performed under controlled conditions. They found that tests done on the serums of 52 proved cases of gonorrheal arthritis "gave 80.7 per cent positive at all times," and they conclude that in cases where the history is consistent with a diagnosis of gonorrheal arthritis a positive test will be correct in 90 per cent of the cases. In about 20 per cent the reaction will be negative.

The committee's report regards the new culture methods utilizing "the oxydase reaction" as more accurate than smears, as described by Gordon and McLeod, 1928, and since modified until in 1934 gonococci were isolated twice as often as from smears. The complement fixation reaction for gonococcus they feel, as we do, should become a routine diagnostic procedure, Myers and Gwynn reporting positives in 86 per cent of 43 cases and McEwen, Bunim and Alexander 98 per cent of a similar series of 43.

Gonorrheal arthritis responds better than does vaginal, cervical or urethral gonorrhea to hyperthermia, but mixed infections have received little benefit in our series. Even slow duration heat treatments, especially if repeated twice or three times a week will clear the arthritis as if by magic, often

leaving the complement fixation and smears still strongly positive.

With regard to the operative treatment of arthritis caused by gonorrheal infections of the pelvic organs, we find wide differences from the mixed type right at the start. We have had a group of cases in which the gonorrheal infection of the cervix has been acute, in another subacute (six weeks to six months) and a third group which may be called chronic, *i. e.*, where the infection had persisted over a period of years with constant reinfection.

Good results have been obtained in all these groups by thorough removal of the cervix, which seems to act as the principal focus, by means of a high enucleation of all the gland-bearing tissue by Sturmdorf's operation.

Cashman at the University of Pittsburgh has obtained equally satisfactory results in acute and subacute arthritis cases by using a deep conical destruction of the gland-bearing area of the cervix by means of the actual cautery.

There is no question in our minds but that in a cervical enucleation by the Hyams' technic using surgical diathermy, less reaction should eventuate in the adjacent structures and still give an adequate result.

The removal of the cervical cone of tissue by means of the Sturmdorf procedure causes local trauma due to traction necessary for proper exposure of the indurated swollen, brawny cervix for removal. In even young multiparae this was followed by a very definite palpable thickening in the parametrium and adnexa. In spite of this distinctly outlined inflammatory reaction, the joint symptoms began to subside immediately after operation. In 2 cases in which the inflammation was fulminating and completely disabling with the patient confined to bed, pain was relieved in five days. One of these was a subacute case and another an extremely acute infection of less than two weeks' duration. After operation, the cervical smears continued positive, but the inflammation in the joints and peri-arthritic tissues subsided very rapidly.

It has been known for a long time that the gonococcus can be cultured from the fluid of swollen joints, and that it does attack the endocardium; but in the tissues of the cervix with its very large, open lymph spaces, the infection may get so

active that little in the tubes has any bearing on the arthritis, the large part of the focal poison partly arising from the fact that the toxins are locked up in the tissues of a brawny inflamed cervix. These 2 cases with their postoperative positive spread, coincident salpingitis, and parametritis, following enucleation of the cervix, and, in spite of all this, a rapid improvement of all joint symptoms, go a long way toward suggesting that the cervix is the really important focus in acute gonorrheal inflammations of the joints and surrounding tissues.

These typical cases in detail are as follows:

**Case VIII.**—A. G. M., aged thirty-seven, housewife. Three months arthritis and periartthritis especially in hips. Spreads negative. Complement fixation negative to 214 different strains of streptococci but positive for gonococcus.

Operation: old cystic cervix removed by Sturmdorf technic. Discharged, walking, five days later. Excellent result at least ten years.

**Case IX.**—L. G., aged twenty-two, maid. Gonorrhea with arthritis of clavicular joints, hands, etc. Spreads positive. Brawny infected cervix removed as above, followed by parametritis, salpingitis, but no arthritis. Spreads positive after operation.

Followed six months, excellent result.

**Case X.**—L. S., aged twenty-one, amateur prostitute, acute gonorrheal arthritis hands and feet two weeks.

Cervix indurated and swollen. Spreads positive.

Relief three days after removal of cervix as above.

Postoperative spreads positive. Parametritis. Salpingo-oophoritis, but no arthritis.

Results: excellent at least one year (lost).

## CONCLUSIONS

1. A certain group of arthritis cases in the female, probably between 6 and 10 per cent, have the most important focus in the pelvis.

2. Some of these will require operative removal.

3. Removal of the cervix in nongonorrheal cases has frequently proved disappointing in our series, as has supravaginal hysterectomy.

4. Removal of the cervical gland-bearing tissue has proved adequate in a number of gonorrheal cases.

5. C. H. Mayo has stated that a residual cervix may need removal if result is unsatisfactory following supravaginal hysterectomy, because it has left part of the focus behind.

6. Complete hysterectomy has given satisfactory results in our hands in fibromyoma uteri, in old infections of parametrium, adnexa, and myometrium, and in pelvic infections of uncertain extent—such as may arise from a badly inflamed cervix on abortion.

7. We have omitted from this discussion a large group of cases involving genito-urinary infection sometimes secondary to pressure of tumors, etc.

8. The newer cultural methods are changing the entire picture in the diagnosis of latent gonorrheal infections and rapidly making less difficult the accurate diagnosis of all gonorrheal arthritis.

## CLINIC OF DR. JOHN A. TAYLOR

### HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### THE UROLOGIC FACTOR IN THE ETIOLOGY AND TREATMENT OF ARTHRITIS

IT HAS been our privilege during the past few years to have been an integral part of the clinic of Dr. R. Garfield Snyder established exclusively for the treatment of arthritis at the Hospital for the Ruptured and Crippled. Every case coming to this division of our urologic clinic has been referred from the arthritis department. In that way we have been able to study a large number of cases of arthritis with the idea of finding a focus of infection in the genito-urinary tracts. Needless to say, all of these cases were examined by the other special departments of medicine and surgery. For the purpose of forming an opinion as to the incidence of the urologic factor in the production of arthritis we have reviewed 1000 consecutive cases seen in this clinic. Cases of frank gonorrheal arthritis are omitted from the study because that class of cases is discussed elsewhere in this symposium.

A careful urologic history is extremely important. We found that in only 5 per cent of the patients who did not admit a past or present relevant history did we succeed in finding a focus of infection. This is a valuable fact for the practitioner who must treat arthritis without the help of a highly organized clinic, for he can decide on the necessity of a urologic consultation, knowing that a negative history will, in approximately 95 per cent of the cases, exclude the genito-urinary tract as a causative factor of the arthritis. In this series, 40 per cent of the cases admitted a genito-urinary history, exclusive of lues which is discussed elsewhere. Of this 40 per cent we were able to demonstrate an infectious focus in 62 per cent of this group.

The urologic examination is always preceded by a general examination. Then an orientation examination is done which includes the examination of the external genitalia—noting particularly the epididymes and vasa for vestiges of old infection. The kidneys are palpated, noting any irregularity in size, shape, or position. The contents of the prostate and seminal vesicles are expressed after a digital examination. Sterile specimens of urine are obtained before and after massage, for regular analysis and cultures. At the time of the examination a drop of the secretion is examined under the microscope and a smear is made. If no pus is seen and the cursory examination appears to be negative, a large sound is passed, followed by the posterior instillation of silver nitrate as a provocative measure. This is followed by a subsequent examination to find any latent focus. If this be negative the patient is advised to prepare himself for excretory urograms.

The preparation for urograms which we have found most effective consists of moderate dehydration, a mild cathartic on the preceding night, an enema in the morning, following with pitressin and a rectal tube for one hour immediately preceding the series. If the urine examinations, including cultures and the slides, are negative, together with negative excretory urograms, the patient is referred back to the arthritis department, with a negative report. If the urine examinations be positive, or, if the excretory urograms show pathologic findings or be unsatisfactory, then a cystoscopic examination is made.

In the treatment of upper urinary tract infection we first attempt to increase elimination from the kidneys and bowels—the colon bacillus being a very common offender. Our results in this type of infection, with the oral administration of the various forms of mandelic acid have been almost startling. Any obstructive pathology, such as strictures at the ureteropelvic junction or in the ureters, calculi, or vesical neck obstruction is removed either transurethrally or by surgery.

In the treatment of seminal tract infection we have not been satisfied with results obtained from the oral administration of mandelic acid or any other drug. Here we need prolonged local treatment at not too frequent intervals, realizing that too vigorous a course of treatment might lead to an acute

prostatitis—sometimes with abscess formation and epididymitis. It is our habit to treat these cases not more frequently than twice a week, more often at weekly intervals. These treatments consist of a gentle stripping of the seminal vesicles and prostate, followed by the posterior instillation of various antiseptic solutions—no one solution being outstanding in all cases. Microscopic examinations of the seminal contents, and urine analysis are done at the time of each treatment.

It is in the treatment of the seminal tract infection that we have obtained the most marked symptomatic relief of arthritis. These results have corresponded with the subsidence of infection in the genital tract. We have also been able to demonstrate better the urologic factor of arthritis in these cases. We recognize a great psychic factor in the treatment of these arthritis cases, but believe there are cases which are very conclusive as to the urologic etiology, two of which we will cite. It is often very difficult to evaluate the benefits of our treatments, for most of these patients are having other forms of treatment which run concurrently—either physiotherapy, diathermy, or special treatments for other foci of infection. Therefore we are deprived of any “post hoc” argument because of the various treatments. However, we do treat some cases at a time when they are obtaining no other form of treatment. These cases have usually been pronounced urologically negative in other clinics and are sent to us only after the treatment of other foci have failed to result in the relief of symptoms.

The first case I wish to cite is that of a forty-four-year-old male who was confined to bed. He complained of pain in the muscles and joints of both shoulder girdles, in the left sternocleidomastoid and trapezius, and in the left metatarsal joints. He had been suffering with these migratory muscle and joint pains for five years—several joint regions being involved successively in each attack. The attacks usually occurred every two to three months. Following the acute pain, swelling and a mild fever usually occurred. In a search for a focus of infection he had had irrigation of his maxillary sinus, tonsillectomy, and extraction of several teeth. He had had a prostatic smear, with no pus, but a *Streptococcus faecalis* on culture. He denied any venereal infection. He had taken salicylates until a gastro-intestinal upset precluded their further usage. This was several weeks before we saw him. His present attack began one and one-half weeks previously.

His general physical examination was negative, except for painful and tender sternocleidomastoid and trapezius on the left side. There was stiffness and pain, on motion, in both shoulder girdles—more marked on the left.

The urologic examination is always preceded by a general examination. Then an orientation examination is done which includes the examination of the external genitalia—noting particularly the epididymes and vasa for vestiges of old infection. The kidneys are palpated, noting any irregularity in size, shape, or position. The contents of the prostate and seminal vesicles are expressed after a digital examination. Sterile specimens of urine are obtained before and after massage, for regular analysis and cultures. At the time of the examination a drop of the secretion is examined under the microscope and a smear is made. If no pus is seen and the cursory examination appears to be negative, a large sound is passed, followed by the posterior instillation of silver nitrate as a provocative measure. This is followed by a subsequent examination to find any latent focus. If this be negative the patient is advised to prepare himself for excretory urograms.

The preparation for urograms which we have found most effective consists of moderate dehydration, a mild cathartic on the preceding night, an enema in the morning, following with pitressin and a rectal tube for one hour immediately preceding the series. If the urine examinations, including cultures and the slides, are negative, together with negative excretory urograms, the patient is referred back to the arthritis department, with a negative report. If the urine examinations be positive, or, if the excretory urograms show pathologic findings or be unsatisfactory, then a cystoscopic examination is made.

In the treatment of upper urinary tract infection we first attempt to increase elimination from the kidneys and bowels—the colon bacillus being a very common offender. Our results in this type of infection, with the oral administration of the various forms of mandelic acid have been almost startling. Any obstructive pathology, such as strictures at the ureteropelvic junction or in the ureters, calculi, or vesical neck obstruction is removed either transurethrally or by surgery.

In the treatment of seminal tract infection we have not been satisfied with results obtained from the oral administration of mandelic acid or any other drug. Here we need prolonged local treatment at not too frequent intervals, realizing that too vigorous a course of treatment might lead to an acute

was having no other form of treatment. In about six weeks he began to show subjective improvement, which coincided with the diminution of pus in the prostatic smear. The clumps of pus had disappeared, and his smear soon showed only 20 isolated pus cells per high power field. After two months he was able to go without his brace. He was very happy over the first relief that he had experienced and decided to go to a warmer climate until Spring, because of his chest condition and his arthritis. This improvement, appearing coincidentally with the clearing up of the urologic focus when he was receiving no other treatment, seems to be conclusive evidence that we were treating the primary cause of his arthritis.

**Summary.**—1. In patients who gave a negative past urologic history, only 5 per cent were found to have a focus of infection in the genito-urinary tract.

2. Forty per cent of the patients admitted a past urologic history, and of these, 65 per cent were found to have infection.

3. Cases like the two cited seem to prove that infections in the genito-urinary tract can be the sole cause of arthritis.

There was pain, on pressure, over the left metatarsus, but no swelling or redness. x-Rays of teeth and sinuses were negative. Our first examination of his prostatic and vesicle secretions showed only a few pus cells and an enterococcus. We found, however, that prostatic treatments precipitated a markedly acute arthritis, with swelling and redness in his right metatarsus. Following our first treatment, the amount of pus in his prostatic and vesicle secretion increased markedly. In a week's time we gave him another gentle treatment and found that it was followed by an acute inflammation in his wrist. This clinical response followed our treatments for three more weeks, after which they became less acute, and finally did not appear. He has been treated for several months; with a great deal of improvement in his arthritis, during which time he had no other treatment. Prior to our treatment, he had never had an interval of more than three months between attacks. This case seems to us conclusive evidence that the prostatitis and seminal vesiculitis were the predominating etiologic factors in this man's arthritis.

The second case is that of a man forty years old. He gave a history of having had gonorrhea seven years previously, without any complications. He had what he thought was adequate treatment, and was pronounced cured. He had been suffering with arthritis in his lumbar spine and left shoulder, for two years. He had been thoroughly gone over in the arthritis clinic, where a hematogenous tuberculosis of the lungs had been discovered and treated, with rest in bed, for two months. There were no tubercle bacilli in the sputum. This condition had been arrested, and he had gained weight and strength. A coccygectomy had been performed for a dislocated and painful coccyx. In spite of anti-arthritic therapy, including physiotherapy and diathermy, his lumbar arthritis had become so acute that he had to wear a back brace in order to get about. He gave no history of urinary disturbance, except that his urine had been "milky." Examinations of the urine at these times disclosed no pathologic findings except mucus.

Physical examination showed a very well-developed adult male, wearing a back brace. Without the brace his discomfort was agonizing. His reflexes were normal. There was a moderate amount of dentistry, but no apical pathology. His chest presented no abnormal signs. His heart had a normal rhythm, with sounds of good quality. The kidneys were palpable, not enlarged, or tender. There were no abdominal masses. External genitalia were negative. There was a general adenopathy, including the epitrochlear nodes. Serologic tests for lues were negative. The prostate, per rectum, was congested. The seminal vesicles were atonic and loaded with debris. A drop of this secretion was loaded with pus. A voided specimen, after massage, showed clumped pus cells with pus shreds, while the specimen before massage showed only a few pus cells. A search for tubercle bacilli in the urine was negative. Cultures of the urine showed a gram-positive diplococcus.

Excretory urograms with diodrast showed good function of the kidneys, which was equal on both sides; no distortion of the pelves; no obstructive pathology or calculi. Treatment of the prostatitis and seminal vesiculitis was carried out, with the emptying of the seminal contents once a week, followed by the posterior instillation of argyrol, acriflavine, *et al.* During this time he

was having no other form of treatment. In about six weeks he began to show subjective improvement, which coincided with the diminution of pus in the prostatic smear. The clumps of pus had disappeared, and his smear soon showed only 20 isolated pus cells per high power field. After two months he was able to go without his brace. He was very happy over the first relief that he had experienced and decided to go to a warmer climate until Spring, because of his chest condition and his arthritis. This improvement, appearing coincidentally with the clearing up of the urologic focus when he was receiving no other treatment, seems to be conclusive evidence that we were treating the primary cause of his arthritis.

**Summary.**—1. In patients who gave a negative past urologic history, only 5 per cent were found to have a focus of infection in the genito-urinary tract.

2. Forty per cent of the patients admitted a past urologic history, and of these, 65 per cent were found to have infection.

3. Cases like the two cited seem to prove that infections in the genito-urinary tract can be the sole cause of arthritis.

### INFECTION OF THE GALLBLADDER AS A FACTOR IN ARTHRITIS

WHEN the rôle of focal infection in the production of chronic rheumatic disease was established upon a rational research basis it was evident that infections of the gallbladder might occupy a prominent position in the etiology of arthritis. Anatomically, the gallbladder would appear to be an ideal nidus for chronic focal infection, yet it has not assumed any such preeminent position.

Cecil and Archer found dental sepsis in 33 per cent and tonsillar infection in 61 per cent of their patients with varying types of chronic arthritis. In a careful study, Hartung and Steinbacher, in 200 patients with chronic rheumatic disease, found only 4.5 per cent with evidence of gallbladder infection. This rate is approximately that of the common incidence of gallbladder disease in the general admission to large hospitals. Twiss and Hanssen in work primarily concerned with disease of the gallbladder considered that such relationship as exists between arthritis and disease of the gallbladder was basically infectious or metabolic. It is apparent that the juxtaposition of the liver prevents many of the general remote and metastatic phenomena of gallbladder infection. The liver interposed between the alimentary circulation and the general circulation, under normal conditions, effectively filters toxins and bacteria from the general circulation. In like manner the liver is the great detoxifying organ and bacteriolytic mechanism in infections of the gallbladder.

Increasing study indicates that the major disability of the gallbladder is due to infection in the wall of the gallbladder.

and both bacteria and their by-products drain into the liver. This infection of the wall of the gallbladder is present in at least 9 out of 10 cases of the gallbladders that are removed at laparotomy. The preeminent bacteria are derivatives of the general group of pyogenic bacteria. In the ordinary case of an infected gallbladder the physiologic competency of the liver for many years is adequate in the control of the sequelae of gallbladder infection. There ensues, however, a gradual diminution in the protective power exercised by the liver and there then begin to be general symptoms due to gallbladder disease and remote manifestations in the form of the nephropathies, cardiopathies and the arthritides. Since the liver exercises so many occult functions it is quite probable the long continued infection of the gallbladder brings about subtle changes in the biochemical mechanism of the body as well as disturbances in the general metabolism. It would appear that many individuals have long continued gallbladder infection and are sensitized or are hyperallergic from the by-products of chronic infection resulting in injury to the joints, tendons, the muscles and synovial membranes. Incidental infections provide a favorable background for arthropathic organisms that arise from points of focal infection other than the gallbladder. Our observations would seem to indicate that the infected gallbladder becomes an etiologic factor in chronic rheumatism only when and if the liver ceases to exercise its full protective capacity. It would appear that the routine removal of gallbladders in patients with chronic rheumatism is a procedure not to be countenanced. The wise procedure would be to survey the patient with chronic arthritis from the viewpoint of disabilities of the liver and biliary system per se and distinct from the arthritic symptoms. If the patient has a diseased gallbladder as recognized by a canvass of the 4 main avenues of inquiry—(1) history, (2) roentgen-ray examination, (3) duodenal drainage and (4) blood chemistry—then the decision as to whether the gallbladder should or should not be removed is entirely dependent upon the diagnosis of the local gallbladder condition.

My personal experience suggests that the patients with chronic arthritis and having a diseased gallbladder are better off by the removal of the diseased gallbladder than they would

be to continue arthritic therapy and retain an infected gallbladder. In brief, the indications for cholecystectomy in chronic arthritis are determined by the pathologic process in the gallbladder and not by the arthritis. One may reasonably expect that approximately 5 per cent of patients with chronic arthritis have a disease of the gallbladder and that in these 5 per cent either the primary or secondary infectious mechanism for arthritis resides in the gallbladder.

THE TREATMENT OF GONORRHEAL ARTHRITIS  
BY PHYSICALLY INDUCED FEVER\*

GONORRHEAL arthritis is a metastatic lesion—the result of a blood stream invasion. It is one of the more frequent, painful complications of the disease. Although spontaneous remissions without residual damage to the joint occur, many patients suffering from gonorrheal arthritis become permanently crippled. Unfortunately, there is no study available to demonstrate how often this occurs.

Until the advent of fever therapy, a constantly increasing variety of treatments was advocated. The number and wide range of therapeutic attempts of the past indicated the failure of any individual method. Our present series of 40 cases had been treated unsuccessfully with other methods prior to fever therapy. In 1 case, removal of tubes and ovaries had not influenced the course of the gonorrheal arthritis. Chemical gonococccides, protein shock with milk, typhoid, whole blood, and intravenous chemicals had been administered in 14 of the cases. A group of 10 of our patients had received gonorrheal vaccines with no permanently beneficial results, and 2 of them were given filtrate which apparently brought on an exacerbation of their arthritis. Local diathermy, immobilization, and other procedures were of no lasting benefit to others.

**Pelvic Foci.**—Despite the prior treatment with gonococccides, all of our patients in this series had active pelvic foci.

\* Much of the clinical material referred to came from the medical services of Dr. George Baehr and Dr. B. S. Oppenheimer, and from the gynecologic service of Dr. Robert T. Frank at the Mt. Sinai Hospital. We desire to express our thanks for their kind cooperation.

In our first series of 16, the 8 females had the following: 8 cervicitis, 6 urethritis, 3 Skene's ducts, 2 adnexitis; of the 8 males, 6 had urethritis and prostatitis, 3 epididymitis, and 2 vesiculitis. In the table of 24 listed below (tabulation), all but 1 of the females had cervicitis, 7 had urethritis, 5 had adnexitis. Two of these cases had peritonitis and very severe systemic manifestations. Among the 13 males, there were 12 with urethritis, 9 with prostatitis, 2 with epididymitis and 1 with vas deferens involvement. As can be seen from the table, the extent of the pelvic involvement did not apparently affect the results. The effectiveness of fever therapy in clearing up the pelvic foci has been described previously.<sup>1, 2, 3, 4, 5</sup>

**Diagnosis.**—Every case included in this series was proved to be an arthritis of gonococcal origin. There are times when the diagnosis of such a specific arthritis presents a baffling problem. Positive bacteriologic or serologic evidence, especially from a joint, establishes the diagnosis. Yet such positive proof is sometimes lacking. Clinical hints of major importance which indicate the necessity for laboratory search for the gonococcus include the following:

(A) *Intensity of pain and inflammatory reaction.* (B) *Mono-articular involvement.* (C) *The rapidity with which the atrophy of the involved tissues progresses.*<sup>6</sup> It is usual for gonorrheal arthritis to start as a fleeting polyarthritis followed by a major involvement of one and occasionally several joints. In our 40 cases, 25 had more than one major joint involvement. Yet when one joint is the seat of an acute involvement, the presence of gonococci should be ruled out.

A patient harboring the gonococcus in the genito-urinary tract may have had or may develop a coincidental arthritis of different origin. It is this type of case which offers the greatest difficulties in diagnosis. There is no one method except recovery of the gonococcus in joint cultures or positive complement fixation of the joint fluid that can establish the diagnosis in such a case. Carpenter, Warren, *et al.*, working at Rochester University Medical School, obtained 80 per cent success with material cultured from bursae and tendon sheaths.<sup>6</sup> The most effective method of isolating cultures from the joint and the pelvic foci was described by some of their workers.<sup>7</sup> The laboratories of the Mt. Sinai Hospital use a similar technic.

Complement fixation of the joint fluid aided us in 2 cases where the organisms were not demonstrated in spreads and cultures from the genito-urinary tract and from the joints.

A positive complement fixation test on the blood is often of help when the history, spreads, and cultures fail in gonorrheal arthritis. The technic used by the Mt. Sinai laboratories under the direction of Gregory Schwartzman was recently modified.\*

Warren, Hinton and Bauer<sup>9</sup> in a thorough study of tests on 316 patients concluded that "a positive (referring to blood complement fixation) in a case in which the history is not consistent with gonorrheal arthritis is not significant. In cases with consistent history a positive will be correct in 90 per cent of the cases. In about 20 per cent of the cases, the reaction will be negative." It must be pointed out that the complement fixation test on the blood is negative when efficient drainage is established or when the formation of antibodies is retarded for other reasons. Special caution must be taken to avoid diagnostic errors when a patient with old or recent gonorrhea later develops a non-gonorrheal joint.

Perfection and standardization of the technic of complement fixation has not been achieved as yet. The findings must be interpreted in conjunction with the clinical picture and other laboratory data. Occasionally repeated tests may be of help. In general, the complement fixation should be used more often as a diagnostic aid, but cannot be relied upon as a major criterion of cure.

**Rationale.**—The progress recently made in the treatment of gonococcal infections by physically induced temperature rises has been due largely to one factor—thermolability of the gonococcus. This organism can be destroyed *in vitro* and *in vivo* at temperatures which human tissues can tolerate safely.<sup>10, 11, 4, 1</sup>

The treatment of gonorrhea and its complications by temperature reactions has long been recognized. Since Wagner-

\* The new method adopted within the past six months is known as the McNeal-Thomson test\* and is used by the New York City Board of Health. It is sensitive and allows quantitative estimation of the complement fixing bodies. A polyvalent antigen consisting of Nos. 15, 42, 8, 34, 32 Torrey strains is utilized. The 37° C. (98.6° F.) fixation method is used.

Jauregg's reports in 1918,<sup>12</sup> various methods for inducing protein shock and temperature reactions were adapted for work in gonorrhea. Satisfactory results with malaria,<sup>13, 14, 15</sup> typhoid,<sup>10, 17</sup> as well as such proteins as milk, peptone, horse serum, etc., have been reported. Local heating of pelvic organs and gonorrheal joints with diathermy also received favorable comment in the past.<sup>18, 2, 10, 20</sup> We have observed that in acute cases the local application to the joints of converse heating as obtained by diathermy and short wave currents may increase the pain and swelling.

Not only can controlled effective heating be applied to the pelvic focus, but the blood stream and metastatic joint lesions can be attacked simultaneously. In addition to the devitalizing and lethal action of heat directly on the gonococcus, there are other important defensive measures evoked by fever therapy.<sup>3</sup> Simpson believes that fever stimulates immune reactions. He cites 4 cases in which patients spontaneously cleared themselves of the gonococcus within a short period after fever treatment. Certain beneficial systemic effects are also achieved with elevations of systemic temperature, such as increased speed of circulation and increased number of white cells and phagocytosis in the blood stream.<sup>21</sup>

The application of physically induced fever for gonorrheal arthritis was an important advance. It permitted the physician to control the height and duration of the patient's temperature reaction at all times. The successful application of this method in gonorrheal arthritis has been the subject of numerous recent reports.<sup>10, 22, 1, 23, 24, 5</sup>

**Technic.**—The technic developed by us was begun seven years ago. We emphasized the necessity for the production of high local temperatures in the effort to eradicate the primary pelvic focus. In this technic, the pelvic organs were heated at 108° to 110° F. for about six to eight hours while the systemic temperature was maintained at about 106° F. and permitted to endure for an additional three to four hours. This technic was a superior one for the treatment of gonococcal infections localized in the pelvis, but in gonorrheal arthritis we occasionally were able to clear only the pelvic nidus, while the metastatic focus in the joints persisted. We have more recently prolonged the period of systemic heating so that the temperature

of 106.5° F. is maintained for a period of twelve to fourteen hours (Chart 1). It is obvious that because of the thermal resistance of some strains of the organism, the higher the temperature and the longer the period of its maintenance, the greater the possibility of one-treatment cures.

For the local elevation of body temperature, we employ a combination of conductive and conversive heating. The patient is placed in what is in effect a horizontal light cabinet which covers the body from the neck down. Underneath the wooden table on which the patient lies (separated by a mattress

of about 3 inches' thickness) are placed 2 large condenser plates each measuring 12 by 14 inches. They are attached to the 6-meter short wave diathermy machine. We usually employ about one half or even a little less of the output of the machine (whose energy is rated at about 400 watts). With this technic we can usually elevate the temperature from 98.6° F. to 106.5° F. within the period of about two hours. Were we to use greater current output, it would be possible to elevate systemic temperature more rapidly. We do not do so, however, because it is our impression that most patients appear to be less uncomfortable when the temperature elevation is

gradual than when it is rapid, and also because of the danger of producing burns when too much current energy is applied.

After the systemic temperature has been raised, we are able to maintain it solely by means of the electric lamps within the cabinet. These are 12 60-watt carbon filament lamps arranged so that 2, 4, or 12 of them may be permitted to shine at one time. In order to avoid burns, should the patient inadvertently bring a foot near the electric lamps (which are guarded by wooden slats), the lower extremities are encased in leggings.

In the female, in order to achieve a more rapid gonococcal influence upon the organisms within the tissues of the pelvis, we apply additional local heating by means of the diathermy current introduced through the instrumentality of a vaginal electrode and 3 dispersive electrodes consisting of metal cuffs placed around the abdomen and around the lower extremities (first around the thighs and subsequently around the calves of the legs).<sup>1</sup>

Water is administered freely to the patients, and if they are willing to take it, 0.6 per cent salt solution. To minimize the discomfort of the treatment, we have found the hypodermic injection of  $\frac{1}{200}$  grain of hyoscine hydrobromide in conjunction with  $\frac{1}{6}$  grain of morphine sulfate to be a very effective procedure. If necessary, because of the patient's restlessness, the administration of a small dose of morphine is repeated during the treatment.

We have found the above technic a satisfactory one, but stress the point that it is strictly a hospital procedure. The only major complications have been occasional burns which, with one exception, have been mild. We consider it essential that, in addition to the nurse technician, a doctor who is experienced in this form of treatment be present during the entire period of temperature elevation. To this we attribute the absence of any major catastrophe in our series of cases.

**Clinical.**—Our cases included 21 males and 19 females, ranging from twenty-one to fifty years of age. The average number of treatments administered to the 40 cases was 2.69. Eight of them had 1 treatment, and all but 1 of these made complete recoveries. The largest number given one patient was 7. The number of treatments required is determined by the thermal resistance of the organism in a given case and by

the height and duration of temperature elevation to which the case is exposed. Lacking the facility to permit the measurement of these factors in advance of the treatment, reliance must then be placed upon the clinical response. When it becomes necessary to repeat the treatment because the thermal attack has been inadequate to destroy the organisms, subsequent treatments should be given as soon as feasible so as to prevent organisms which may have been attenuated from gaining their full virulence. Practically speaking, this means that treatments should not be spaced further than one day apart where

Chart 2.

possible. Some workers believe that those organisms persisting after bouts of fever become more heat resistant.<sup>25</sup>

**Response to Treatment.**—The response of the systemic and joint manifestations of nearly all of the cases to treatment was satisfactory and frequently dramatic. Temperature elevations subsided (Chart 2), malaise, chills and sweats when present disappeared. Red cell sedimentation rates showed trends to normal (Chart 3), and patients were able to get out of bed within a short period after treatment. Joint symptoms in all but 8 of the 40 subsided with remarkable uniformity immediately after the termination of the treatments. In all

cases, including these 8, there was a definite change for the better.

Of the 24 cases outlined in the tabulation, 14 had all evidence of their pelvic and joint involvements permanently eradicated within twenty-four hours after treatment. They are listed under "cured." Of the 16 previous cases, this was true of 7. The others required adjuvant treatments for varying lengths of time. These included short courses of chemical gonococicides and various procedures to speed healing of the

Chart 3

injured tissues of the joints. It should be noted that organisms not killed by fever appear to be attenuated so that short courses of chemical after-treatment ranging up to three weeks eliminate the original focus.

Listed under slight improvement in the table are 5 cases in which there were varying degrees of persisting pain and immobility and positive bacteriologic findings. Of the original 16, 3 cases had similar persisting symptoms. Of these 3, 1 patient required four months of after-treatment for complete restoration of painless function, and the other 2 came for treat-

ment with permanent bony ankylosis (x-ray evidence). Of the 5 in the series outlined above, one male (J. F.) refused more than one treatment. Another female (L. J.) had recurrence of pain and positive smears three weeks after discharge from the hospital. In her case, the recurrence occurred at home, and we have not yet established whether there was a reexposure with her former consort.

The remaining 3 (B. Sw., M. B., S. A.) had treatments which we now consider inadequate. Their temperature elevations were but  $105^{\circ}$  and  $106^{\circ}$  F., maintained for too short a period—five to six hours. We feel certain that these were not failures of method, but failures in our technic. Most of the 250 strains isolated by Carpenter<sup>7</sup> and his coworkers can be killed at temperatures of  $106.7^{\circ}$  F. in from eleven to twenty-one hours (75 per cent of cases). It is the rare case that requires more than twenty-one hours and becomes difficult to treat by this method. Retreatment at  $106.7^{\circ}$  F. for ten to fourteen hours should materially increase the number of rapidly cured patients.

A factor affecting response is the duration of the disease before treatment. Generally, we have found that the longer the chronicity before treatment, the less rapid is the response to treatment. The danger of permanently damaged joints also increases with chronicity. Finally, after-treatments to restore completely joint function (diathermy, short wave, baking, massage and under-water corrective exercises) are more apt to be necessary in the chronic cases.

**Follow-up.**—The importance of follow-up work in gonorrheal arthritis is self-evident. As a rule, we follow our cases for one year. The results must always be checked against time and the laboratory. One valuable aid in gauging the response is the sedimentation rate. Although the complete return to normal may take six weeks, the fall in accelerated rate is a definite indication of subsidence of the infection and inflammatory process. The delay in return to normal probably is due to the gradual absorption of residual debris and slow healing of previously acutely inflamed tissues.

**Conclusion.**—Of 40 cases of gonorrheal arthritis treated by means of temperature elevation induced by physical means described, 32 showed a dramatic restoration to normal. Eight

were complete or partial failures. In our opinion, except in those cases where the existing pathology precludes the possibility of improvement, as in bony fusion, failure is due not to the method, but to the inadequacy of the technic with which it is applied. From our experience with physically induced fever therapy, we feel that it is the treatment of choice to be used at the earliest available opportunity in gonorrheal arthritis.

## CLINIC OF DR. SAMUEL KLEINBERG

### HOSPITAL FOR JOINT DISEASES

---

#### TUBERCULOUS ARTHRITIS

IN a brief consideration of tuberculous arthritis it seems advantageous to limit oneself to a review of those elements which have practical significance. From this point of view it will be of value to discuss the diagnosis and treatment of tuberculous disease of bones and joints, for the joints are rarely involved without sooner or later an extensive invasion of the bones forming the joints.

#### DIAGNOSIS

**General Considerations.**—Tuberculous arthritis is a disease of slow and insidious onset and a chronic course. Characteristically and most often the disease is monarticular. In a minority of cases two or three joints are affected and in rare instances there may be many joints simultaneously involved. There are numerous significant factors in the patient's family and past history and in the general physical examination which contribute much to the establishment of an exact diagnosis. *First* among these is a family history of tuberculosis. An active or even an arrested tuberculosis in other members of the family with whom our patient has been in intimate contact makes it extremely likely that he has contracted the disease. Several weeks ago I saw a child six years old with an arthritis of the left knee. No other joints were involved and the x-ray film of the left knee was negative. But the history revealed that this patient's father had died and a younger brother was now ill of pulmonary tuberculosis. It was, therefore, more than likely that the disease of the left knee was tuberculous. *Second* is a history of preexisting or coexisting tuberculous disease in other

tissues. A year ago a man was referred to me for an arthritis of one knee. The history showed that this man had had Pott's disease which was arrested by a spinal fusion and a tuberculous kidney which had been removed. This information compelled the suspicion of tuberculous disease of the knee. This was confirmed at operation. *Third*, since a tuberculous arthritis is but a local manifestation of a systemic disease, there may be x-ray evidence of present or past pulmonary invasion or disease of the hilar glands. *Fourth*, the occurrence, especially in children, of some acute debilitating illness as measles or scarlet fever is likely to be followed by the appearance of a tuberculous focus. *Fifth*, trauma to a joint predisposes it to a tuberculous process. All statistics are in accord that there is a history of a definite trauma in about 50 per cent of bone and joint tuberculosis. *Sixth*, the location of the arthritis helps in the differential diagnosis. An inflammation of a temporomaxillary joint is, as a matter of experience, not likely to be tuberculous, while a chronic destructive inflammation of the spine, hip or knee, in the absence of manifest evidence to the contrary, is very apt to be tuberculous.

#### CLINICAL SYMPTOMATOLOGY

**Pott's Disease.**—Pott's disease or tuberculous spondylitis is the most common of all tuberculous bone and joint lesions. The most significant early subjective symptoms are pain in the back, weakness of the back and awkwardness in walking. Objectively we find an angular projection of the spine at the site of the disease, muscle spasm, rigidity of the spine and tenderness to pressure over the diseased area. The symptoms vary in their appearance and degree according to the location of the lesion. In the dorsal or most common site the deformity may progress to a very noticeable degree before the subjective symptoms become evident. The deformity or kyphos may be the first symptom to be observed. In the cervical region, on the other hand, where there is very free motion, even a small lesion leads to marked symptoms. In the lumbar region, too, the subjective symptoms appear earlier than the objective changes. As the disease advances the deformity increases. In the dorsal area as many as 6 or 8 vertebrae may be diseased. With their collapse a marked angulation of the spine takes

place, the trunk is shortened and the chest may be telescoped into the pelvis.

The two most frequent complications in Pott's disease are abscesses and paralysis. An abscess forming about the diseased area seeks an outlet along the tissues that offer the least resistance. Thus in the cervical area the abscess may appear in the retropharyngeal space or in the lateral aspect of the

Fig. 119.—Dorsal Pott's disease. Shows marked kyphos. Support by the hands and by plaster leg bandages indicates that this boy had had paralysis from which he is recovering.

neck. In the dorsal region the abscess may remain in the vicinity of the diseased vertebrae or burrow down along the front of the spine. Commonly the abscess extends downward and forms a psoas abscess, raising the psoas muscle from the ilium and causing a flexion contraction at the hip. It may extend under Poupart's ligament and appear in the thigh. Not infrequently the abscess extends posteriorly and is found

on the back. In the lumbar region the abscess may extend backward into the loin or buttock or downward under the psoas and into the thigh. Psoas abscesses may reach very large proportions, filling the lower abdominal quadrants and causing marked bulging of the abdomen.

Paralysis appears most commonly in dorsal Pott's disease. It is due to invasion of the spinal canal and pressure on the cord by tuberculous granulation tissue, inflammation of the meninges or a "cold" abscess. The earliest evidence is weakness of the lower limbs, instability in walking, exaggeration of the patellar and ankle reflexes with marked ankle clonus. If the disease is below the reflex center of the legs the paralysis is

Fig. 120.—Convex frame used for the support and correction of Pott's disease.

flaccid with complete loss of all reflexes. The extent of the paralysis is not related to the degree of the deformity.

**Hip.**—The earliest symptoms are lameness, disinclination to be active and pain in the thigh and knee. The pain in the knee is due to pressure on the obturator and anterior crural nerves which are distributed in the thigh. Early in the disease the symptoms are present only when the child first begins to walk and disappear after an hour or two. After some months, however, the symptoms are continuous and increasingly disabling. A limp appears very early. The limp and disability are due in the primary stage to sensitiveness of the hip on weight bearing and in the later period to the deformity arising from fixed flexion of the hip and shortening of the limb. There is a variable degree of limitation of all motions. Muscle spasm

becomes specially apparent on attempting to move the limb. There is a fulness in the groin and sensitiveness to pressure over the hip, particularly anteriorly. One or more abscesses may appear. These usually point anteriorly or laterally, but also occasionally in the buttock.

An x-ray picture of the hip will show at first an indistinctness of the bony outlines. Later there is an irregular destruc-

Fig. 121.—Nov. 2, 1931. Extensive tuberculous process of the hip. Femoral head almost completely absorbed. Acetabulum is diseased and enlarged

tion and absorption of the femoral head. The whole of the femoral head may disappear and even part of the neck may be destroyed. The acetabulum may be invaded, usually the upper part becomes irregularly destroyed and enlarged, permitting upward displacement and even dislocation of the femur.

**Knee.**—As in other joints the disease appears insidiously and progresses slowly. The knee becomes swollen and painful, causing a limp and disability. Night cries are common in

children. As fluid accumulates in the joint the knee becomes flexed and this deformity remains unless corrected. There is usually local heat and tenderness to pressure over the knee. There is marked muscle spasm and restriction of motion. As the disease increases the knee becomes more flexed and deformed. The leg may be subluxated backward. The x-ray pictures show in the early stage only a general haziness. Later there is seen a subchondral rarefaction and destruction and absorption of the articular cartilage of the femur and tibia.

Fig. 122.—Nov. 5, 1935. Same patient as in Fig. 121. Shows healing effects of fusion of the hip joint

The patella is involved very late and always to a much less degree than either the tibia or femur. In the last stages one sees irregular excavations in the condyles of the femur and the tuberosities of the tibia.

**Ankle.**—Tuberculous disease in the ankle joint is less frequent than in the other weight-bearing joints. Its onset and course are similar to those in the knee. The ankle becomes slowly enlarged and increasingly painful. There is a limp. Muscle spasm is present, limiting motion. There is local heat

and tenderness. Abscesses may rupture leaving sinuses. The foot tends to become fixed in plantar flexion. The x-ray picture shows haziness at first and later a variable degree of destruction of the adjacent surfaces of the tibia and astragalus. The tuberculous disease commonly invades the bones of the ankle joint but may involve any or several of the tarsal bones.

Fig. 123.—Tuberculous disease of the knee. Shows extensive erosion of femoral condyles and tibial tuberosities.

**Shoulder.**—This joint is affected much less often than the weight-bearing joints. Clinically the joint becomes swollen, stiff and painful. There is marked muscle atrophy and limitation of motion. Abscesses do not often appear, hence the disease is sometimes called "caries sicca." As the lesion advances, the arm becomes fixed to the side of the chest with complete loss of abduction. In the early stages the x-ray picture is not characteristic of any disease. The head of the humerus appears mottled and the articular surfaces undisturbed. Later the

Fig. 124.—Caries sicca of shoulder. Extensive destruction of humerus and glenoid process of scapula.

Fig. 125.—Extensive tuberculosis of elbow. Shows marked erosion of humerus, ulna and radius

roentgenogram shows a destructive process in the head of the humerus and the glenoid process of the scapula.

**Elbow.**—There is a tendency in this joint for early extensive bone destruction and abscess formation. The symptoms are similar to those in other joints. There is persistent and increasing swelling and pain, muscle spasm, limitation of motion, local heat and tenderness. The x-ray picture in the early stages may be negative, except for infiltration and swelling of the soft tissues. In the later stages one sees all gradations of bone destruction in the adjacent articular extremities of the humerus and ulna and lastly of the radius.

**Wrist.**—This joint is comparatively rarely affected by tuberculosis. Its clinical symptomatology includes swelling, pain, disability, local heat, tenderness and atrophy of the hand and forearm. The roentgenogram in the early stages is negative, but as the disease advances it shows bone destruction involving the radius, ulna and several of the carpal bones.

#### LABORATORY AIDS IN DIAGNOSIS

The clinical picture in a chronically inflamed joint may present strong presumptive evidence of tuberculous disease. The roentgenogram may show a destructive bone lesion which confirms the suspicion of tuberculosis. But we should attempt to establish a positive diagnosis, for in certain joints, particularly in adults, a positive diagnosis of tuberculous arthritis warrants a major operation as a means of arresting or eradicating the local process. The measures at our command for establishing a positive diagnosis are the following:

1. **Tuberculin Tests.**—There are 3 tuberculin tests, namely, the von Pirquet or epidermal, the Mantoux or intradermal and the subcutaneous injection of diluted old tuberculin. A positive epidermal or intradermal test means that the individual has an active or latent tuberculous focus. It does not signify that the inflamed joint under consideration is tuberculous, but it is extremely likely to be so, especially if the clinical evidence points in that direction. The subcutaneous test, when positive, yields a local reaction, a systemic response by a rise in temperature and malaise and, significantly, a focal reaction by a temporary increase of the symptoms in the suspected joint.

2. **Aspiration of Fluid from the Joint.**—Whenever possible some fluid ought to be aspirated from the joint. It may

reveal tubercle bacilli and thereby establish the diagnosis. If no tubercle bacilli are found the fluid ought to be injected into a guinea-pig.

**3. Guinea-pig Injection.**—The guinea-pig is very susceptible to tuberculous infection. The fluid removed from an abscess or preferably from the joint is injected into the abdomen of the guinea-pig. If the fluid is tuberculous the guinea-pig will develop tuberculosis and succumb to it. Microscopic examination of the organs of the animal will reveal tuberculosis.

**4. Biopsy.**—This involves exposing the diseased tissue by operation and requires at least a local and often a general anesthetic. It, therefore, should be resorted to only when the other tests fail or are inconclusive and the proposed therapy is predicated on an absolute diagnosis. A biopsy permits visual inspection of the joint and removal of tissue for microscopic investigation. This test when positive is helpful. Yet conceivably the lesion may be tuberculous but the particular specimen removed may not contain either tubercles or tubercle bacilli.

### TREATMENT

The treatment of tuberculous arthritis falls into two divisions, namely, general and local.

**General.**—As tuberculous arthritis is but a local manifestation of a systemic infection, the patient must primarily and continuously receive the therapy that is appropriate and necessary for all cases of tuberculosis. This includes rest of the body and mind, forced feeding, an abundance of fresh air, and if possible living continuously outdoors.

**Heliotherapy.**—Heliotherapy, by gradually increased exposure of the whole body to either the sun's rays or to artificial ultraviolet rays, is today accepted as an important modality for improving the body tone and increasing the patient's resistance to tuberculosis. Not all are in accord with Dr. Rollier of Switzerland, the distinguished and notable exponent of heliotherapy, who believes that the sun's rays are specific in curing tuberculosis. Dr. Lo Grasso of this country is also an ardent advocate of heliotherapy properly administered and in combination with supportive and medical treatment. My experience convinces me that there is unquestionably a whole-

some and tonic effect from a well-regulated system of air and sun baths which increases the resistance to disease.

**Local Treatment.**—All local treatment has 3 objectives: (1) arrest of the disease, (2) reduction of the existing deformity, (3) prevention of increase of deformity. These objectives are obtained by immobilization of the diseased area and the application of various corrective measures by traction, postural treatment, manipulative procedures and operations. The local treatment is best considered in relation to each joint.

**Pott's Disease.**—The essential in the treatment is rest of the diseased vertebrae. In children it is best obtained by keeping the patient on a convex frame in hyperextension. This position prevents increase of the deformity and is simultaneously effective in reducing the deformity. Furthermore, the recumbent position removes the irritating and crushing effects of the superincumbent weight of the spine and trunk on the diseased area, present when the patient is standing. Instead of a convex frame one may use sand bags, a plaster bed or a plaster jacket. Many surgeons advocate a fusion operation on the spine at all ages to provide an internal splint. Experience, however, shows that in children such an operation does not cure the disease. Unless the trunk is supported and protected adequately for a very long time the disease will continue and the deformity increase. Consequently in Pott's disease in children we must depend chiefly upon prolonged immobilization for the arrest of the disease.

In an adult with Pott's disease a spine fusion is advisable as soon as the diagnosis is established. The effect of the operation is very different from that in a child. Actual fusion of the vertebrae is readily obtained and favors a rapid arrest of the disease. Subsequently the spine ought to be protected by external apparatus for at least a year.

**Complications of Pott's Disease.**—*Abscesses.*—When these are small and cause no annoyance no treatment is necessary. When the abscess is large or threatens to rupture it should be emptied, preferably by aspiration, repeated as often as may be required. If the contents of the abscess are so thick that they cannot be removed by aspiration, an incision is permissible, but the wound must be promptly sealed by suture. When sinuses appear they are best treated by simple surgical

dressings. This simple treatment of cold abscesses and tuberculous sinuses applies wherever and whenever they are found.

*Paralysis.*—This infrequent complication of Pott's disease is most effectively treated by placing the patient, child or adult, in bed, preferably on a convex frame. Recovery fortunately occurs in most cases in one to six months. In the exceptional instance it may be necessary to do a laminectomy for relief of pressure on the cord.

*Hip.*—The chief element in the treatment is rest of the joint. This can be obtained by keeping the patient in bed, splinting the hip by a plaster support and applying traction to separate the diseased surfaces. Immobilization of the hip prevents increase of the deformity. When there is a flexion and adduction deformity this may be corrected by traction or by gentle manipulation under an anesthetic. The conservative local treatment for the hip must be continued, as in the case of the spine, over many months and years, until all symptoms subside and there is radiographic evidence of fusion of the femur and ilium. Our aim must be to obtain a bony fusion, for so long as there is any motion in the hip relapse is likely and deformity inevitable.

Appreciating the importance of eliminating all motion in tuberculosis of the hip, fusion by operation is now very extensively practiced at all ages, even in very young children. Experience proves that a fusion of the hip favors arrest of the disease. It is sometimes difficult to obtain a fusion, especially in children, but we should seek to obtain it through an operation unless this is contraindicated. In the adolescent and in the adult with tuberculosis of the hip it should be our primary aim to perform the operation as soon as possible. Healing occurs rapidly in these tissues and the outlook for arrest of the disease is even more favorable than in children. Abscesses are a common complication and should be treated expectantly until by their size they cause inconvenience or they threaten to rupture, when they must be aspirated.

*Knee.*—In the adult the ideal treatment is an arthrodesis, that is, an operation for the eradication of the disease by removing the articular ends of the femur and tibia and contacting healthy bone. The bones become united and the diseased process subsides. We may confidently look forward to an ar-

rest of the local process within six months, permitting the individual to return to a gainful occupation within a year. In the young child it is difficult to obtain bony fusion. In addition there is the disadvantage of disturbing the epiphyses by the operation and thus causing a shortening of the limb. It seems best, therefore, in very young children to adhere to a conservative program. The knee ought to be immobilized either in a brace or in a plaster support, and the period of immobilization continued for many months and years. During this period one has to be on his guard to maintain the knee in complete extension, for there is a strong tendency for it to become flexed. If there is already a flexion deformity this should be corrected by traction or by gentle manipulation under an anesthetic. Tuberculous or "cold" abscesses about the knee occur fairly frequently and should be treated expectantly, as they are in other parts of the body. When they reach a size that blocks motion or when they show signs of impending rupture they should be aspirated.

**Shoulder.**—In children the arm should be supported by some form of abduction apparatus, holding the limb in about 70 degrees of abduction at the shoulder, slight outward rotation and slight flexion. The immobilization should be continued for several years, if necessary, until there are no signs of any active inflammation and the joint appears to be securely ankylosed. In the adult the treatment of choice is an arthrodesis. When the humerus and scapula are fused the inflammation of the surrounding tissues subsides rapidly and the individual is left with a very useful limb. The loss of motion in the shoulder causes only moderate inconvenience since it is replaced by a compensatory range of scapulothoracic motion.

**Elbow.**—Since disturbance of the various epiphyses about this joint would cause serious loss of substance and length in the arm and forearm, it is advisable, in children, to adhere to a program of conservative treatment, carried out by rest and immobilization of the elbow in flexion, which is for the elbow a useful position. When abscesses and sinuses appear they should be treated in the same manner as was outlined for other joints. In the adult tuberculosis of the elbow should be treated by an arthrodesis, fusing the joint in flexion. This is a sound treatment and yields good results. In this nonweight-bearing

joint some splendid results have been obtained by a wide excision of the diseased portions of the humerus, radius and ulna, leaving a pseudarthrosis. By this operation we gain 2 things, namely, the diseased tissue is removed, and a satisfactory range of motion is retained. The decision as to which operation shall be performed must be left to a conference with the patient, and depends in a large measure upon the patient's social and economic status and occupation. In a laborer an ankylosis is by far the more desirable choice. On the other hand, for a young woman not engaged in strenuous work, an excision of the diseased tissue permitting a useful range of motion may be the best form of treatment.

**Wrist.**—In children, conservative treatment by support of the forearm and hand by a splint or brace is the only treatment permissible, since any kind of surgery would result in permanent damage of the bones and permanent disability. Often tuberculosis of the wrist is but a part of an extensive tuberculous arthritis and none but conservative measures may be warranted. In the adult, if the disease is limited to the wrist and there are no contraindications, an operation for arthrodesing the wrist is permissible.

#### SUMMARY

Tuberculous arthritis is a disease of common occurrence. Of 4626 orthopedic cases admitted to the indoor services of the Hospital for Joint Diseases during 1934 and 1935, 22 per cent had tuberculous lesions. Our primary aim must be to establish a positive diagnosis. This is accomplished by correlating the history of the course of the lesion, the patient's family history, the patient's past history, the clinical manifestations of the arthritis and the results of the laboratory tests. When a positive diagnosis has been made, treatment is promptly instituted. This consists of *general measures* for the enhancement of the patient's resistance, *heliotherapy* for its tonic effects and for whatever specific healing influence it may have on the tuberculous lesion and *local therapy* to the affected joint. The details of the local treatment depend on the joint involved. We seek primarily to rest the joint by prolonged immobilization, since freedom from function favors healing of the inflammation. Sometimes, as in the spine in adults, it is possible by an

operation to provide an internal splint. This assures fixation and rest of the joint which favors an arrest of the disease. In some joints as in the knee and elbow one can eradicate by operation most of the diseased tissue which hastens the process of healing. The main element, however, in the treatment of the majority of cases is long-continued protection of the joint by some form of apparatus.

#### PNEUMOCOCCAL ARTHRITIS

PNEUMOCOCCAL infection of the joints is an extremely rare condition occurring only about once in 1000 cases of pneumonia. Bulkley<sup>1</sup> in 1914 compiled 173 cases from all available sources. In one series there were 17 joints in 12,400 cases of pneumonia. During the period from 1918 to 1932 at Guy's Hospital, Fagge<sup>2</sup> found only 7 cases. Cecil, Baldwin and Larsen<sup>3</sup> reported the occurrence of 8 pneumococcal joint infections in 1913 cases of pneumonia. Of these, 5 were due to pneumococcus type 1, 1 to pneumococcus type 3 and 2 to pneumococcus group 4. At the Hospital of the Rockefeller Institute over a period of twenty-five years only 2 infected pneumococcal joints, 1 pneumococcus type 1 and 1 pneumococcus type 3, were noted in about 1800 cases of pneumonia. There was 1 other case noted, an atypical type 2 infection adjacent to a shoulder joint but not penetrating the joint.

Cameron<sup>4</sup> has reported the occasional occurrence of pneumococcal arthritis in young infants. Many joints may be involved simultaneously or in succession.

Most of the cases of pneumococcal arthritis occur as a complication of pneumonia. A small proportion occur in association with pneumococcal septicemia without pneumonia. As a complication of pneumonia, usually one joint is involved, the knees most commonly, more rarely the shoulders, wrists and elbows.

In pneumonia, when a joint becomes red, tender and swollen, a metastatic infection may be expected and aspiration of the joint confirms the diagnosis. There are no signs or symptoms which enable one to diagnose a pneumococcal joint from any other type of acute arthritis.

Most cases showing this complication are critically ill and not only the pneumonia itself, but other complications as meningitis and pericarditis cause the death of the patient. In the very rare case where the patient survives the pneumonia and in those cases without pneumonia, recovery takes place with complete restoration of joint function.

When the joint is aspirated, direct smears of the purulent fluid as well as cultures on blood agar should be made. Occasionally sterile cultures are obtained on early aspiration of the joint and repeated aspirations may be necessary to establish the diagnosis.

Previous joint trauma may be a factor in the localization of the infection as in Fagge's<sup>2</sup> case of a young man, who after spraining an ankle and then acquiring an upper respiratory infection, developed a pneumococcal abscess of the affected ankle.

Farah<sup>5</sup> described a very unusual case of a man who, over a period of ten years, had recurrent attacks of arthritis in one of which pneumococcus type 3 was recovered from the blood. He made a complete recovery and though aspiration of the affected joints was not permitted, serologic examinations seemed to confirm the diagnosis. It is possible that the joint symptoms in this case were allergic and not a true infection of the joints.

If aspiration and later surgical drainage of the infected joint are not instituted, the intense inflammatory reaction of the synovial membrane goes on to thickening of the subsynovial fibrous tissue and destruction of the synovial surface cells and cartilage may ensue. On the other hand, with adequate treatment, no permanent joint or bony changes may take place and there is no final functional disability.

## CLINIC OF DR. CARLISLE S. BOYD

### WILLARD PARKER HOSPITAL

#### ARTHRITIS OF SCARLET FEVER

ARTHRITIS is not an infrequent complication of scarlet fever. It is often spoken of as "scarlatinal rheumatism" or "arthritis of scarlet fever." This type of arthritis is of a non-suppurative nature. The lesion consists of involvement of the synovial membrane, with a slight amount of serous effusion into the joint and some periarticular swelling and thickening. The fluid is sterile.

In 5549 cases of scarlet fever seen at the Willard Parker Hospital during the four years, 1933 to 1936 inclusive, there were 99 cases of arthritis. This does not include cases of arthritis due to serum sickness or caused by rheumatism. The incidence of the scarlet fever arthritis was as follows:

	<i>Total Scarlet Fever Patients</i>	<i>Cases of Arthritis</i>	<i>Percentage</i>
1933	1056	23	2.18
1934	1349	39	2.89
1935	1672	23	1.37
1936	1472	14	0.95

The incidence for the total cases was 1.78 per cent. Excluding the year 1936, when convalescent serum was used in many cases, its occurrence in 4077 cases was 2 per cent.

It is recognized that the frequency of this complication varies in different epidemics. The figures given here are much lower than those cited by many writers. The use of scarlet fever antitoxin or convalescent serum in the severer cases and the fact that scarlet fever in New York is much milder than it was ten or more years ago would explain the low incidence in this series as compared with older statistics.

This complication occurs more often in older children and adults than in early childhood. Although the number of cases of scarlet fever in patients ten years of age and under is more than twice that seen in those over ten years of age, there were only 40 cases of arthritis in that age group, whereas there were 59 cases in older patients. It occurs more often in females than in males; there were 70 cases in females and 29 in males.

While arthritis may occur any time in the course of the disease, it usually makes its appearance at the latter part of the first week or early in the second week—most often from the fourth to the tenth day. The joints most frequently involved are the small joints of the hands, wrists and knees, less often the shoulders and ankles and occasionally the elbows and hips. The tendency is for symmetrical joints to become involved either simultaneously or one shortly after the other. Sometimes as the pain lessens or disappears in the joints first attacked, other joints become affected. Rarely, after subsidence of the condition, in a week or more there is a recurrence, which is usually of shorter duration than the initial attack. In this series, the average number of joints involved was three or four.

Pain is the most characteristic symptom and varies in severity. In some cases it may be accompanied merely by fever. The pain is usually fairly severe and is increased by active or passive motion of the involved joints. Some complain of moderate pain and stiffness and but little tenderness. In other cases, in addition to the pain, there is more or less definite swelling and a certain amount of tenderness. There is some effusion into the joint and a variable amount of periarticular involvement. Increased heat or redness may be present. When the hands are involved, tenosynovitis is not infrequently seen. Fever is a rather constant accompaniment of the joint involvement. There is usually a steplike rise to  $101^{\circ}$  to  $102^{\circ}$  F., then in mild cases the temperature is remittent and in the severer cases maintained at  $102^{\circ}$  to  $103^{\circ}$  F., with a return to normal by lysis. At times the elevation of temperature occurs from six to eighteen hours before the patient complains of pain or any evidence of joint involvement is noted. More often it occurs about the time that the patient complains of joint pains and lasts until the joint symptoms subside.

The duration of the arthritis is usually from two to five days. In exceptional cases it may last for two weeks. The cases which develop early in the disease are usually more severe than the later ones.

Treatment consists of rest of the affected joints, methyl salicylate externally and the internal administration of salicylates. Locally, relief is usually afforded by the application of gauze saturated with methyl salicylate 1 part, olive oil 5 parts, or an ointment such as:

R Methyl salicylate	2½ drachms
Petrolati	q. s. ad. 2 ounces

spread on a piece of linen or several thicknesses of gauze and placed over the affected joints, which are then wrapped with nonabsorbent cotton or cotton batting or flannel. The affected parts should be supported in the most comfortable position by means of pillows, small cushions or bath towels.

Salicylic acid preparations have proved of value in relieving this condition. A child five years of age may be given sodium salicylate 5 grains every three or four hours; a child of ten years, 10 grains every three or four hours; an adult, 20 grains every three hours. An equal amount of sodium bicarbonate may be given with the sodium salicylate. Salicylates should be given well diluted and not on an empty stomach. When sodium salicylate is not tolerated by the stomach, acetylsalicylic acid (aspirin) may be used. A five-year-old child may be given 5 grains every three or four hours; a ten-year-old child, 7½ grains every three or four hours; an adult, 10 grains every two or three hours. The dosage of these drugs must be guided by the effect produced. As the symptoms subside, the dose should be lessened. When salicylates are not borne by the stomach, they may be administered by rectum. Then the daily amount of the drug may be divided into two doses and given morning and evening. The patient should receive a saline enema and one-half hour later the salicylate mixed with 4 ounces of starch paste should be given slowly into the rectum, using a funnel and small rectal tube or catheter.

#### DISCUSSION

There is a difference of opinion as to whether or not the joint involvement in scarlet fever is a manifestation of rheu-

matism. The arthritis of scarlet fever is more prone to attack the smaller joints than is rheumatism. In the 40 cases in children ten years of age and younger, 110 joints were involved. The hands, wrists and ankles accounted for 78 of the 110 joints. The most common manifestation of rheumatic disease in children is endocarditis. If the arthritis seen in scarlet fever was of rheumatic origin one would expect endocarditis to be frequent. Not a single case was seen as a complication of scarlet fever in this series. Furthermore, in a rather extensive experience, the writer has never seen a case of endocarditis caused by scarlet fever as such, although rare cases have been reported.

A patient with active rheumatic fever may contract scarlet fever just as may any individual; then no definite relationship between the two diseases can be said to exist. The writer has seen many patients with chronic rheumatic cardiac disease pass through scarlet fever without active rheumatic manifestations. Occasionally, however, we see an activation of definite rheumatic disease during the course of scarlet fever. A child may show no evidence of rheumatic fever at the time of occurrence of scarlet fever and either during the course of or immediately following scarlet fever may develop rheumatic cardiac disease. This may be explained by the activation of a latent rheumatic disease by the streptococcus of scarlet fever. Two such cases were seen on my pediatric service at the New York City Hospital during the past two years. One case came to autopsy. Much further study and follow-up of patients is required before the relationship of the two diseases can be definitely answered.

It is my belief that endocarditis occurring in the course of scarlet fever is almost invariably of rheumatic origin and a careful study of the history, course and follow-up will prove it to be such. The rare exception may be an endocarditis, part of a pancarditis, in septicemic cases. The writer believes this nonsuppurative type of arthritis seen in scarlet fever is of toxic origin and is not a manifestation of rheumatism.

**Suppurative arthritis** is a rare complication of scarlet fever. Three cases occurred in this series of 5549 cases. All were in severe types of the disease and were part of a general sepsis, the blood cultures showing hemolytic streptococci. In

(Seven patients with generalized or fleeting pains excluded.)

one case, the left knee joint was involved; in another, the left knee and right wrist joints, and in the third case the metacarpophalangeal joint of the right index finger.

The affected joints are painful, swollen, reddened, hot and tender. The fever is high and the usual symptoms of septicemia are present. Two of these patients received scarlet fever antitoxin early in the disease and all received repeated transfusions. Fortunately, the 3 patients recovered.

In this type of case, scarlet fever antitoxin, convalescent serum, sulfanilamide and transfusions are aids in saving life.

The treatment of the suppurative joint is surgical. Incision and drainage is usually followed by more or less impairment of function of the joint, especially when the knee joint is involved, and requires the services of an orthopedic surgeon.

### ARTHRITIS IN BRUCELLA MELITENSIS INFECTIONS

**Comparative Pathology.**—*Brucella melitensis* infection is primarily a disease of domestic animals. Man becomes involved surprisingly infrequently through the contacts necessary in caring for these animals or through the handling or use of food products from these sources. Though the general clinical manifestations of *Brucella melitensis* infection in man and animals appear to vary widely, the pathologic processes have striking similarities. Orchitis, for example, is a complication common to various animal species and to man, and mastitis which occurs so frequently in cattle is observed occasionally in man. Arthritic manifestations may also be studied in both animals and humans.

There are 3 varieties of *Brucella melitensis*—the *melitensis* (or caprine), the *abortus bovine*, and the *abortus porcine*. These may be readily differentiated culturally, through the bacteriostatic action of certain dyes. Reasonably accurate classification may also be obtained through noted variations in pathogenicity for animals. The *abortus bovine* variety, which but rarely involves animals other than cattle, produces the mildest infection with few complications. The porcine and caprine strains, both of which may also infect cattle, tend to produce severer diseases, though with some variations in pathologic manifestations. All of these varieties are encountered in the United States. The *melitensis* strains are limited largely to the goat-raising areas of the Southwest, the porcine to the hog-raising states of the Middle West, but the bovine is disseminated widely in all parts of the United States.

The frequency of arthritic manifestations parallels the general severity of these infections. In guinea-pigs inoculated with bovine strains complications of this nature are rare. In our own experimental studies with the porcine strain, suppurative arthritis and spondylitis were relatively common. *Melitensis* infections, as described in the literature compare, in this regard, with the disease produced by the porcine varieties.

In natural infections in swine also, arthritis is not uncommon. The joint or joints become swollen, and are obviously painful. In these destructive lesions of bones and joint surfaces are found. In cattle, on the other hand, the joint may become markedly swollen, but evidently without pain. Here bone involvement is lacking and the aspirated fluid is serous. From such lesions *Brucella melitensis* *var.* *abortus* (bovine) has been isolated. It is by no means established, however, that similar arthritic manifestations may not arise from a variety of causes.

***Brucella Arthritis in Man.***—The frequency and nature of arthritis in undulant fever varies widely, dependent on the variety of the organism involved. As in animals so in man, this complication is rather rare in the milder infections caused by the bovine strains. In disease produced by porcine strains such involvements are rather common, but evidently less so than *melitensis* infections observed in the Mediterranean regions. In Iowa where about one third of the infections were of porcine origin, arthralgia was a symptom noted in 36 per cent of the cases, but was a prominent complaint in but 7 per cent of all. Characteristically, multiple joints were involved, with the pain shifting from one joint to another. In order of frequency, those involved were knees, elbows, ankles, shoulders, wrists, fingers and toes. Usually there was no detectable physical abnormality. Only occasionally were the joints swollen, red and very painful. In 1 case we observed, as others have described in the literature, the massive and relatively painless swelling of an hydrarthrosis. These complications usually developed late in the disease and occasionally only in convalescence. Complete subsidence without residual manifestation was the rule.

That an eroding suppurative arthritis is caused by *Brucella* infection of man (as is true of animals) is also well established. The frequency of this is as yet quite undetermined. We have

observed such lesions only in the spine and wrist joints. In clinical character these closely simulated tuberculous involvement and undoubtedly are commonly so diagnosed. A more frequent consideration of *Brucella melitensis* infection is clearly warranted in such cases.

**Diagnosis.**—Of first importance in the diagnosis of all types of *Brucella* infections is a wider appreciation that these organisms are very widely distributed in nature and that man is frequently exposed. If considered seriously, a correct diagnosis of undulant fever and its complications is usually attained. The aid of the laboratory is essential. A normal or low white blood count is of material aid in differentiating from pyogenic infections. A positive serologic test is highly reliable, but in chronic disease a negative finding is not conclusive. Bacteriologic studies, especially of suppurative lesions, are indicated but these are quite unreliable unless the peculiar cultural requirements are appreciated. Skin tests and the opsonophagocytic reaction in the hands of workers, experienced with this infection, are also of some aid.

## CLINIC OF DR. ARTHUR KRIDA

### BELLEVUE HOSPITAL

---

#### ACUTE SUPPURATIVE ARTHRITIS: RECOGNITION AND TREATMENT

THE orthopedic surgeon, having to deal so often with the consequences of joint suppuration, is led to inquire whether some of the more unfortunate results of such suppurations may not be to a great extent minimized or prevented by, in the first place, early recognition of the seriousness of the disease and in the second place, by more attention to the details of its treatment. The complications of joint suppuration in the order of their importance may be stated as follows: (1) death; (2) chronic suppuration with discharging sinuses and chronic toxemia; (3) bony ankylosis with or without deformity; (4) joint disorganization with painful limitation of motion usually with deformity; (5) temporary stiffness of the joint with gradual recovery of function.

Into which of the above categories the outcome of an individual case will fall will depend in the first place upon the virulence of the infecting agent, in the second place upon the resistance of the individual and in the third place upon the treatment accorded that case.

The early symptoms of acute joint suppuration are fever, pain, swelling of the joint with effusion, limitation of movement of the joint by muscle spasm, and tenderness on pressure about the joint. The effusion is purulent in character and not infrequently will yield the causative organism on culture. As the process develops, the effusion gradually becomes less and is eventually replaced by general infiltration. The average time period for these changes is from three to four weeks in an untreated case. At this time, the joint has been converted into a cavity containing debris and a small amount of exudate, and

the synovial membrane has been converted into inflammatory granulation tissue. The articular cartilages have been invaded and this invasion may have gone on to complete destruction with infection of the underlying bone ends. The abscess may in the meantime burst through the capsule and become evacuated either by incision or spontaneous rupture. A period of chronic suppuration ensues which is accompanied by great pain and toxemia. In such a joint bony ankylosis is apt to be the outcome.

It will be at once apparent that it is important that the grave character of the process be recognized at an early stage, if the joint is to be salvaged.

From a review of numerous case histories of suppurative arthritis, it is striking to note how frequently these cases are considered as rheumatic fever or cases of milder types of infectious arthritis. The manifestations of suppurative arthritis are much more severe than those of most mild types of joint infection. Indeed, the pain is frequently so great that the patient is apprehensive not only about being moved about in bed but apprehensive about the slightest movement of the bed clothes or of the bed. The outstanding aid in the diagnosis is aspiration of the joint and the examination of the exudate.

The importance of joint aspiration can hardly be overestimated. It is a harmless procedure which yields valuable information and is frequently of great therapeutic value as well.

The *x-ray* is unfortunately of no value as an aid in the diagnosis of the early phases of joint suppuration. In the later phases, the *x-ray* is of great value in assessing the amount of joint damage which has taken place. The most striking *x-ray* finding in the intermediate phase of joint suppuration is lessening of the joint space as shown in the film. This is a direct measure of the extent of damage to the articular cartilage and is of great value in the prognosis of the probable outcome of the case. The *x-ray* also is of value in the elucidation of those rather uncommon cases in which joint invasion has been secondary to a focus of osteomyelitis in the neighboring bone.

Treatment of acute joint suppuration should have 3 things in mind: (1) the treatment of the active infection; (2) the "long look ahead" about the attitude of a joint destined to ankylosis, and (3) the treatment of the sequelae.

In dealing with acute joint suppurations the practitioner is apt to place too much emphasis upon the discovery and control of the focus of infection and too little upon the local treatment of the infected joint. This is an eminently proper attitude to adopt in dealing with gonorrheal arthritis but in nearly all other joint infections, valuable time is lost by searching for a remote cause in an infecting focus while the damage is progressing within the joint.

Gonorrheal infection is the exception to this general observation. It has long been recognized that the control of the genito-urinary infection exercises a favorable influence upon the course of the arthritis. The newer methods of treatment by hyperpyrexia have only served to emphasize this older clinical observation.

A purulent exudate within a joint should be evacuated as promptly and as completely as possible. In most cases this can be accomplished by aspiration and lavage through the aspirating needle and this process may be repeated as often as the exudate reaccumulates.

In that minority of cases where aspiration is unsatisfactory or not feasible, the abscess in the joint should be incised and drained.

With reference to incision and drainage of joints, it may be stated that a considerable variation in details of management is discovered in practice. The ideal situation is one in which the joint is opened by one or more incisions, a rubber tissue sutured to but not within the capsule, and motion instituted, as in the Willems method. In actual practice this ideal is probably less often realized than one would hope.

In those severe cases in which, despite drainage, infection progresses, and the knee joint is a typical instance, and it appears that the limb might have to be sacrificed, it is at times wise to open the joint widely by an anterior horseshoe incision, flex it to a right angle and expose all parts of it for drainage and application of antiseptic solution. In such cases, as the infection subsides the joint is gradually straightened and ankylosis allowed to take place in a favorable attitude.

"The long look ahead" may be approached from 2 standpoints: (1) those joints in which recovery with preservation of motion is to be looked for, and (2) those joints in which

bony ankylosis or great limitation of motion is to be anticipated.

1. Those joints in which recovery with motion is to be anticipated should be handled with a judicious mixture of rest and motion. An inflamed joint primarily demands rest but with care and ingenuity a certain increasing amount of motion may be instituted and by this means shorten the convalescence and limit joint stiffness.

2. Joints which by the nature of the infection and the general clinical background are assumed to be destined to ankylosis need fixation by splintage in the most favorable attitude for that particular joint. This is a truism which should not need repetition, but the orthopedic surgeon has so frequently to deal with the results of the neglect of this principle that his point of view may be a little distorted and he may be pardoned for the reiteration.

## CLINIC OF DR. T. LLOYD TYSON

FROM THE DEPARTMENT OF MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, AND THE ARTHRITIS CLINIC OF THE PRESBYTERIAN HOSPITAL\*

---

### SPONDYLITIS ANKYLOPOIETICA

THIS disease, perhaps better known as Marie-Strümpell spondylitis or Bechterew's disease, is a primary synovitis of the intervertebral joints, with subsequent calcification of the ligamentous structure and eventual rigidity of the spine. In moderately advanced cases it presents a characteristic clinical and roentgenographic picture which cannot be confused with other ankylosing diseases of the spine.

First described by Marie, Strümpell and Bechterew at the end of the last century, the disease aroused a great deal of interest and controversy because of certain differences in description insisted upon by these authors. Bechterew described the disease as one starting in the cervical region and progressing caudad, while Marie and Strümpell reported initial involvement of the lumbar spine with subsequent extension cephalad. It is now generally agreed that these differences are merely of localization of the disease and that the fundamental process is the same in each.

Spondylitis ankylopoietica, while not common, is encountered much more frequently than is ordinarily supposed. Buckley collected 150 cases in six years. During a five-year period. Anton Fischer reported 98 cases and Erlich reported 260. In the Arthritis Clinic at Presbyterian Hospital 1 case is encountered to about every 13 cases of rheumatoid arthritis. It is primarily a disease of adolescents and young adults, but

\* The Arthritis Clinic of the Presbyterian Hospital is supported by The Faulkner Memorial Fund.

may occur at any age. The average age of onset in Buckley's cases was thirty years. The sex distribution is striking and has been commented upon by all authors. It is predominantly a disease of males and Freund states that he has seen only 1 instance of the disease in a woman. It is generally agreed that it occurs from six to ten times more frequently in men than in women. Not infrequently it affects 2 or more members of the same family. Marie reported a similar disease in cats.

Pathologically the process begins as a synovitis of the small intervertebral joints. This is accompanied by osteoporosis of the vertebral bodies and if the disease begins in the lumbar region, a synovitis of the sacro-iliac joints. In those cases in which the process begins in the cervical and thoracic spine, costovertebral synovitis is an early change. Later, calcification occurs in the longitudinal ligament, the ligamentum flavum and the lateral borders of the intervertebral disks, giving the characteristic bamboo appearance to the spine. Involvement of the intervertebral, costovertebral and sacro-iliac joints frequently gives rise to destruction and ankylosis. Exostoses rarely occur and then only secondarily. It will be seen that this is a totally different picture from that of osteo-arthritis of the spine with osteophyte formation and bridging. According to Elliott, Virchow was the first to differentiate these two great groups of arthritis of the spine; osteo-arthritis, a degenerative process occurring in the aged and spondylitis, an infectious process in the young.

The finding of arthritis elsewhere is common and has been commented upon frequently. Involvement of the pelvic and shoulder girdles is particularly apt to occur and led Marie to call the disease "*spondylose rhizomélisque*." The smaller joints of the extremities are also occasionally involved, presenting the typical changes of rheumatoid arthritis. In these cases the process invades the joints in a centrifugal order, beginning at the root joints and extending peripherally. In Fischer's series 29 per cent had such involvement. Because of this and the fact that so many of these patients have a past history of acute rheumatic fever or other evidence of rheumatism, the majority of clinicians believe that spondylitis ankylopoietica is simply rheumatoid arthritis of the spine and its cause the same as that

of rheumatoid arthritis elsewhere. Hench and Bauer in a recent review of the literature voice this opinion and our experience at the Arthritis Clinic of Presbyterian Hospital is confirmatory. There are, however, many who believe Marie-Strümpell spondylitis may be the result of many etiologic factors, among them typhoid, gonorrhea, rheumatoid arthritis, trauma and various infections. There is one significant fact that seemingly supports this concept, namely, the sex incidence. If spondylitis ankylopoietica is purely rheumatoid arthritis of the spine why should it occur so predominantly in males, while rheumatoid arthritis occurs three times more frequently in females? When we search clinical experience, however, we find a similar discrepancy in sex distribution in the manifestations of another disease. This comparable situation exists in the case of chronic alcoholism and the Korsakoff syndrome. In both conditions the etiology is alcohol, but according to Draper, Korsakoff's syndrome is seven times more prevalent in females even though alcoholism is six times more frequent in males.

Our experience at the Presbyterian Hospital has definitely indicated that the incidence of neisserian infection in patients with spondylitis ankylopoietica is no higher than its occurrence in patients with other diseases. When it does occur there has been no apparent relationship between the two. It would seem probable that the cause of spondylitis ankylopoietica is an unknown infectious process as in rheumatoid arthritis and that the same factors, undue fatigue, focal infections—especially with the hemolytic streptococcus—debility and familial history of rheumatism frequently pave the way to the establishment of both diseases.

The roentgenologic features of Marie-Strümpell spondylitis are characteristic and, in the more advanced stages, pathognomonic. Here, too, one finds a similarity to rheumatoid arthritis. As pointed out by Taylor *et al.*, the roentgenologic changes are similar to those noted in cases of rheumatoid arthritis, except for the anatomic distribution. The earliest change is general decalcification, followed by haziness in the intervertebral joints of the spine. Oblique films are often necessary to demonstrate this. In well over 90 per cent of cases a definite early x-ray finding is obliteration of the sacroiliac joints and this testimony, together with general osteo-

porosis, should make one suspect the diagnosis. As the disease advances osteoporosis with coarse trabeculation becomes more

Fig. 126

Fig. 127

Fig 126 —An advanced case, showing calcification of ligaments with the characteristic bamboo appearance

Fig 127 —A lateral view of Fig 126

marked and calcification of the ligaments of the spine and of the outer borders of the intervertebral disks occurs. Finally the intervertebral and costovertebral joints becomes ankylosed

and the spine then becomes one continuous rigid unit (Figs. 126, 127). In only the very advanced cases, however, is the whole spine involved. Usually the process limits itself to one or another section.

The clinical signs and symptoms are variable, depending upon the acuteness of the onset and the localization of the process. In the majority of cases the onset is insidious, but in about 10 per cent it is acute.

In the acute form the symptoms may come on abruptly with fever, leukocytosis, high sedimentation rate and agonizing pain. The pain is due to actual involvement of the nerve trunks by the inflammatory process as well as synovitis of the joints of the spine. It is usual to find root pains as well as back pain. Sciatic pain is a common occurrence and was present in about 40 per cent of Krebs' cases. If the lower dorsal roots are involved the pain may be indistinguishable from that of renal colic or an acute abdomen. Areas of hyperesthesia frequently may be demonstrated and pressure or tapping over the spinous processes causes severe pain. Rigidity of the spine is usual with marked spasm of the paravertebral muscles. Transitory lower motor neurone paralyses also occur and where sciatic pain is severe the Kernig sign may be positive. Due to involvement of the costovertebral joints there occurs in some instances severe respiratory pain which may simulate pleurisy.

In such cases the disease may run its course in a few months leaving the patient with a completely ankylosed "poker" spine and marked wasting of the musculature; or it may assume a subacute or chronic form. This type of onset is more apt to occur in the young and occasionally is complicated by typical mitral stenosis, a finding which favors the opinion that spondylitis ankylopoietica, like rheumatoid arthritis, is related to rheumatic fever.

Far more frequently the onset is insidious with fleeting, variable pains and increasing stiffness of the spine. Frequently during the early stages such diagnoses as lumbago, neuralgia or sciatica are made until time makes the correct diagnosis evident. With advancing activity of the disease the patients lose weight, sometimes as much as 30 or 40 pounds in a year, the stiffness becomes more marked and thoracic respiration gradu-

ally becomes lost. It is then the patient develops the characteristic carriage and movements which make it possible to diagnose his condition from a distance.

Fixation of the spine invariably occurs in the position the patient habitually assumes. If the onset and course are acute and the patient in bed, the resulting ankylosis is straight. In ambulatory patients fusion is most apt to take place with the development of a well-marked dorsal kyphosis and loss of the normal lumbar lordosis. Despite the extreme degree of pain and crippling which this form of arthritis leads to, the prognosis is not as bad as one might expect. Death from the disease is a rare occurrence and somehow, these patients make an adjustment to their disability and frequently live to old age.

The treatment of the disease is the same as that of rheumatoid arthritis and may be divided into general and specific measures. As the disease is a general debilitating infection general measures should include adequate rest and attempts to build up the individual's general resistance. A high vitamin, high caloric diet, large doses of cod liver oil, iron, removal of foci of infection, and salicylates for pain are the most beneficial measures. Transfusions are frequently valuable even when the anemia may be only moderate. Vaccines, gold salts and hyperthermia, while recommended by some, have been, in our experience, rather disappointing. The specific measures are orthopedic in nature and are most important to prevent deformities. A stiff spine in good position is not a severe handicap and can be attained in most cases where the diagnosis is made early. To accomplish this, patients should be fitted with a spinal brace to be worn during the day and instructed to sleep on the back at night. A board should be placed between the mattress and spring and no pillow used. Deep breathing exercises should be taken often to prevent the loss of thoracic respiration. Surgery, such as spinal fusion, is contraindicated.

Finally, it should be emphasized that any patients complaining of generalized pain, especially in the back, shoulders or sciatic region, with an elevated sedimentation rate, should be suspected of having Marie-Strümpell spondylitis and should have roentgenologic study to confirm or rule out this diagnosis.

## CLINIC OF DR. LEWIS CLARK WAGNER

### HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### CHRONIC BONE ABSCESES (BRODIE) SIMULATING SYMPTOMS OF ARTHRITIS

**Introduction.**—Arthralgia is most likely to be associated with intra-articular pathology which may be transitory or dependent on more permanent changes which produce alterations in the periarticular structures, synovial membrane, and articular cartilages. Arthralgia caused by definite extra-articular pathology is rare, and can only be through sympathetic reactions in the adjoining structures. Chronic metaphyseal bone abscess may be the hidden cause at times for such symptoms.

In 1842, Sir Benjamin Brodie described certain findings which today are quite a common occurrence. It might be pertinent to quote his words: "Chronic inflammation, producing a chronic enlargement of the epiphysis, is a not infrequent occurrence, and is liable to be mistaken for disease in the joint itself; the more so, as inflammation of the synovial membrane sometimes occurs as a secondary disease. Occasionally, chronic inflammation of an epiphysis terminates in the formation of an abscess in the center of the bone, but contiguous to the joint. An abscess of this kind is attended with an extraordinary degree of suffering."

It is interesting to note that occasionally amputation has been resorted to, but we know today the treatment is considerably more simple when the exact pathology is noted.

**Etiology and Pathology.**—The cause of these abscesses is the result of an epiphysitis. Therefore the beginning arises in the younger years of life when the epiphyses are patent. The latent infection becomes active with the resultant localized abscess formation. The condition is always chronic, never acute. These abscesses, because of their chronicity, cause sclerosis in the surrounding bone structure as compared to a

very acute inflammation, such as if induced by virulent pyogenic organisms. One finds acute necrosis rather than any acute abscess formation. Nonvirulent staphylococci are most likely to be responsible. In the first or quiescent stage, there is a cavity filled with serum and lined with a membrane like the periosteum of young bones. When the mature stage of the abscess arises, the lining membrane is converted into granulation tissue and the cavity becomes filled with staphylococcus pus. The outer layer of granulation tissue erodes and the abscess becomes progressively enlarged. As the bone is eroded within, new bone is formed. If pus formation is more rapid than bone erosion, there is tension and pain, but if bone erosion is sufficiently rapid to prevent tension, there is little or no pain. In the final stage, the abscess perforates the bony shell on the periosteal surface or into an adjacent joint.

**Symptoms.**—The symptoms are often difficult to differentiate and are most often thought to be rheumatic in origin. Pain is ever present and can be usually controlled by aspirin. Irregular sweats with occasional fever may be present. The harassing pain causes sleeplessness, exhaustion and, at times, emaciation. There is partial loss of function to the affected joint and occasionally there is an accompanying synovitis. The tenderness is marked even when pain is absent. *The pain is not in the joint as the patient suspects, but is at the site of abscess.*

The following 3 case histories are presented in order to show the symptoms are not unlike arthritis and had been treated as such until pathology was noted.

### RÉSUMÉ OF CASES

**Case I.**—Oscar J., aged twenty-four, admitted to the hospital May 9, 1936

For the past eight years, patient has had pain about the right shoulder and extending to the arm. He has been treated continuously for rheumatism. The pain seemed to be centered in the shoulder joint itself and radiated backward to the scapula. In the beginning, the pain did not trouble him in the daytime and it was noted only in the early morning which would cause him to get up and walk about. He has had a thorough search for foci of infection. Tonsils and teeth have been removed and to date the pain has been continuous. It is necessary for him to take certain amounts of codeine daily.

**Examination** is negative except for the right shoulder. The right shoulder girdle shows moderate atrophy. There is, however, no restriction of motion except in abduction. He does handle the shoulder joint with care. There is

moderate atrophy of the biceps muscle. The bicipital region in the right measures  $10\frac{1}{2}$ , and the left  $11\frac{1}{2}$ . The right forearm measures 9, left  $9\frac{1}{2}$ . There is no tenderness about the scapula or shoulder joint except about the head of the humerus. Posteriorly, there is no tenderness. With the arm in neutral position in the region of the subscapularis muscle close to the axillary plexus, there is some thickening and marked tenderness on palpation.

*x-Rays* of this region (Fig. 128) show a definite rarefaction circumscribed in the medial aspects of the humerus about 1 inch from the shoulder joint. There is considerable calcium laid down on the outer surfaces of this area.

*Diagnosis.*—Chronic bone abscess (Brodie), right upper humerus.

Fig. 128.—A, x-Ray showing area of rarefaction in head of humerus prior to operation B and C, x-Ray postoperative, showing cavity filled in with new bone.

*Operation.*—The right humerus was explored. A small window was made in the medial and anterior surface of the humerus and the abscess cavity located. It was filled with a gelatinous reddish-looking material which was curetted out. All rough edges were removed and the wound closed without drainage. Patient made an uneventful recovery from operation and volunteered the information the following morning that his old pain was gone. x-Rays taken two years later show the cavity to have filled in with new bone, and the patient is symptom free.

*Comment.*—Analysis of the above pain findings could lead one to suspect a brachial plexus syndrome, either by pressure

or inflammation of the nerve roots. The tenderness and atrophy of the arm and the slight restriction of motion lead one to suspect arthritis. The true cause of pain was noted only by the x-ray findings.

*Case II.*—Russel DeS., aged twenty-four, admitted to the hospital December 10, 1934.

Patient is a British West Indian, who for the past five years has had pain in the left hip joint region. Pain at times radiated to the hip and ankle and

Fig. 129.—Preoperative x-ray shows area of necrosis about lesser trochanter of femur

he had considerable difficulty in walking. He had some restriction of motion, especially external rotation of the hip. Pain had been intermittent in character and was partially controlled by aspirin. For the past ten months, pain has been almost unbearable. He has consulted a great many physicians and x-rays were taken and called negative.

*Examination* reveals patient to be in splendid physical condition. There is no evidence of polyarthritis about the terminal joints. Examination is concentrated on the left lower extremity. There is moderate atrophy of the left thigh and patient walks with a left limp. There is restriction of external rotation and extension of the left thigh. There is some tenderness on deep palpation in the region of the lesser trochanter. Forced movements give the patient

pain. A thorough laboratory examination reveals blood count, blood chemistry and urine within normal limits. Spinal fluid, normal pressure, protein 27, and manometric examination normal.

*x-Ray* of the entire body showed nothing unusual except in the region of the lesser trochanter of the left femur (Fig. 129) about 1 inch from the hip joint, a definite rarefaction at the base of the lesser trochanter, measuring about 1 cm. in width with sclerotic changes in the surrounding bone was noted.

*Diagnosis.*—Chronic bone abscess (Brodie), left femur.

*Operation.*—The following morning, the left hip joint region was explored through an anterior incision. Definite sclerotic changes were noted in the periosteum about 1 inch above the lesser trochanter. A window was made in the bone in this region and an abscess cavity was encountered. The cavity was filled with a seropurulent material and considerable semisolid drainage. Cultures from the wound were negative and microscopic examination of the fragments of bone and granulation tissue revealed necrotic bone and chronic inflammation. Patient was examined two years later and has complained of no further pain. Normal motion has been restored to the hip joint and he has gained about 20 pounds in weight.

*Comment.*—Analysis of the above pain findings leads one to suspect a sciatic syndrome, the pain in the hip being caused by an inflammation of the lumbosacral roots, as there was only slight limitation of motion in the hip and the tenderness of the hip joint could not be noted because of overlying musculature. The diagnosis of arthritis was suspected. Because the patient took aspirin continuously, drug addiction was considered and only by *x-ray* study was the nature of the lesion discovered.

Case III.—Rupert Z., aged thirty-four, admitted to the hospital June 30, 1930.

For fourteen years he has had swelling in the region of the internal malleolus. It has been associated with attacks of pain from time to time which laid him up for one or two days. The pain at times has almost been unbearable and his treatment has always been for arthritis. Tonsils have been removed. His gastro-intestinal tract has been explored. Many teeth have been removed without any improvement. Six weeks prior to admission to the hospital, he had had a very severe attack of increased pain, swelling and heat around the ankle and was unable to continue with his work. Examination at that time showed patient to be in good condition and in considerable pain.

Examination was negative except for the right lower leg. There was considerable thickening and swelling about the ankle joint. The greatest edema seemed to be around the internal malleolus. Motions of the joint were markedly limited. He had no temperature.

*x-Ray* showed a definite rarefaction in the lower end of the tibia (Fig. 130). There was marked periosteal thickening. This rarefaction measured about 1 X

1½ cm. The abscess cavity was very close to, if not communicating with, the ankle joint.

*Diagnosis.*—Chronic bone abscess (Brodie), lower end of the tibia.

*Operation.*—The following morning, the internal malleolus was explored through a longitudinal incision. There was moderate thickening about the periosteum. A small window was made in the tibia and the abscess cavity entered. Definite seropurulent material exuded and on culture revealed *Staphylococcus albus*. The wound was thoroughly curetted. All loose bone removed and, because of the acute inflammation at the time, the wound was drained.

*Reexamination* in April, 1937, seven years after operation, revealed that the patient has been pain free, with normal motions in the ankle. Swelling

Fig. 130.—A, Preoperative x-ray showing cavity with necrosis in internal malleolus and lower end of tibia. B and C, x-Ray (postoperative seven years) showing cavity filled with new bone

has disappeared and to date both ankles measure the same in circumference. There is no disturbance of motion in the ankle joint and x-ray shows consolidation of the bony cavity.

*Comment.*—Analysis of the above findings leads one to think only of chronic monarticular infectious arthritis with acute exacerbations. It is strange that patient suffered eighteen years (three years in war duty) and no physician suggested x-ray by which the diagnosis was made.

*Diagnosis.*—The diagnosis of these chronic abscesses is at times most difficult, but one should hold in mind the ever-present possibility. Extensive x-ray studies of the bones in

various positions should be made. One can often overlook the pathology in overexposed films and x-rays taken for bone detail are always indicated. On several occasions, I suspected an abscess, but it could not be demonstrated by x-ray until many films had been taken. The constitutional symptoms are few, if any, except a loss of weight, and this fact is only noted because, after operation, the patient seems to gain weight in every case. The abscess usually occurs near the upper margin of the metaphysis of the bone. One can find localized tenderness on pressure and percussion, hydrops of the adjacent joint, local enlargement of bone and superficial veins. The persistence of "boring" pain, referred to a joint and center of affected bone, atrophy of the extremity, slight limitation of motion in certain directions, the control of pain by aspirin, can lead one to suspect the presence of a chronic bone abscess.

**Treatment.**—Once the diagnosis made, the treatment indicated is surgical drainage. The cavity is explored through a small opening in the bone and the bone cavity is evacuated of its serum, seropus, or gelatinous reddish granulation tissue. The edges of the cavity are thoroughly curetted and all rough edges smoothed off. As the contents of the cavity are sterile in most instances, the wounds are closed without drainage. No further treatment is indicated. The relief of pain is spectacular and, when operation has been accurately done, there is no recurrence.

## CLINIC OF DR. ALAN DEF. SMITH

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

### DIFFERENTIAL DIAGNOSIS OF CONDITIONS CAUSING PAIN IN THE LOWER BACK

Case I.—The patient is a young man of twenty-two whose complaint is pain in the lower back. His first recollection of this symptom is that he had

FIG 131.—Case I. Lateral x-ray of the lumbosacral region, showing posterior displacement of the fifth lumbar vertebra on the sacrum.

a severe pain nine years ago after wrenching his back, at which time he was in bed for two weeks. There was no recurrence until four years ago, when

again he strained his back by lifting a heavy weight. This caused him to go to bed for one week. Since then he has had intermittent attacks of pain, some of them very severe, precipitated by bending forward, lifting heavy weights or doing any kind of hard work. His back feels weak and is easily fatigued. He was seen for the first time in the clinic in December, 1934. *x*-Rays were taken of the lumbosacral region, which revealed anteroposterior articulations between the fifth lumbar and first sacral vertebrae and a posterior displacement of the fifth lumbar on the sacrum. He was provided with a belt and exercises were prescribed. These had little effect in relieving his pain, which has continued and has been getting progressively worse. A spine fusion of the fifth lumbar vertebra to the sacrum was advised and he has been admitted to the hospital for this procedure.

We see a stocky, healthy appearing young man with good muscular development. Physical examination shows nothing of importance except in the lumbosacral region. He stands without deviation of his trunk to either side, but tends to list over toward the right when he bends forward. There is no limitation of motion in the lumbar spine. Motion is equally free in the sitting position. We now have him lie prone on the examining table. There is localized tenderness over the spinous process of the fifth lumbar vertebra and the ligament between this and the first sacral spine, but none over the sacro-iliac joints or the lumbar or gluteal muscles. Flexion of the knees with the hips extended is not limited. Compression of the iliac crest causes no pain and there is no pain from hyperextension of either thigh with the opposite hip fully flexed. (This is called the Gaenslen sign and is a test for sacro-iliac arthritis.) Flexion of the hips with the knees extended is neither limited nor painful.

A lumbar puncture was done and it was found that the spinal fluid was clear and under normal pressure. No cells were found in the fluid and the total protein content was 20 mg. per 100 cc. Spinal punctures are now done as a routine on all patients who are to be operated on for low back pain, in order to eliminate cases of spinal cord tumor or other lesions within the spinal canal.

This case is typical of a back which is structurally weak because of the nature of the development of the lumbosacral joint and which is incapable of withstanding the stresses to which it normally is subjected. With such a history of long repeated attacks of pain and failure of conservative treatment to relieve the condition, spine fusion is indicated and is the only means that we have of effecting a cure.

Several factors combine to make the lumbosacral junction a weak area in *Homo sapiens*. In the first place, he has not yet become completely adjusted to the upright posture and the change in stresses which this has brought about. The lumbosacral joint is at the junction of the anterior lumbar and the posterior sacral curves, and of the movable with the fixed por-

tion of the spine. The structure of this part of the skeleton has not become sufficiently stable in pattern to be uniform, and there are numerous developmental variations, many of which tend to detract from the strength of the joint. Among them are the following:

The lumbosacral angle, which is the inclination of the superior surface of the sacrum from the horizontal, is normally about 42 degrees. When it exceeds that figure, or in other words, when the upper surface of the sacrum approaches more nearly the vertical plane, the shearing strain, which tends to make the fifth lumbar vertebra slide forward on the sacrum, is increased, and this often results in pain.

The direction in which the facets of the lateral articulations face is of great importance, and varies considerably at this level. The normal internal-external or sagittal type of lumbar joint enhances stability. When these articulations are anteroposterior, or coronal, they are much less stable and are vulnerable to injury. Asymmetrical articulations are particularly liable to result in low back pain.

Posterior displacement of the fifth lumbar vertebra on the sacrum, although usually of only slight degree, is common and a very frequent cause of low back pain. Because with this displacement the canals through which the fifth lumbar nerve roots emerge from the spine are made smaller, sciatica often results from pressure on these roots.

A forward displacement of the fifth lumbar vertebra, or spondylolisthesis, also occurs frequently, but not as much so as the posterior one. It is caused by a congenital defect or failure of union in the laminae of the fifth lumbar vertebra, usually between the upper and lower lateral articulations. The condition usually causes pain, although often not until adult life.

Because an evolutionary trend is active in the lumbosacral area, producing a shortening of the trunk by the migration of the pelvis upward, we find many individuals who have transitional lumbosacral vertebrae which have some of the characteristics both of lumbar and sacral vertebrae and which give rise to mechanically unstable joints.

Lesions of the intervertebral disk between the fourth and fifth lumbar and first sacral joints may cause a protrusion of the cartilage into the canal with resulting pressure on the cauda

equina and nerve roots, or may so upset the normal mechanics of the lumbosacral joint as to cause strain and traumatic arthritis.

These are some of the more common structural variations in this region which must be looked for in searching for the cause of low back pain. Needless to say, good *x*-rays are essential and must include both lateral and anteroposterior views.

**Case II.**—D. G., a man, thirty-five years old, began to have pain in the lower part of his back one year ago. It was intermittent and not severe. Three months later pain started in his right buttock, back of the right thigh, and outer side of the right leg. This became increasingly severe and for two weeks prior to his admission he had to remain in bed.

He is a tall man with well-developed muscles. All movements of his back are very limited and painful and he can stand only with great difficulty. There is marked spasm of the sacrospinalis muscles and his trunk lists to the left side. Tenderness is marked over the right sacro-iliac joint and gluteal muscles. The patient is placed on his left side and the left hip and knee are flexed sufficiently to obliterate the lumbar lordosis. The right leg is then grasped just below the knee and the thigh is abducted and extended while the pelvis is steadied by the left hand. The right lower extremity is then allowed to drop toward the table as far as it will, care being taken not to allow the hip to rotate externally. In this case the thigh remains in abduction and the maneuver increases the patient's pain. He then is turned over on his right side and the test is repeated with the same result, except that it causes pain on the right, or opposite, side to the one being tested.

This test is the one described by Ober to demonstrate contracture of the fascia lata. Ober discovered the existence of this condition in a case of sciatica and complete cure followed the division of the contracted fascia above the trochanter. Since then several hundred patients have been operated on for this condition with good or excellent results in from 75 to 80 per cent. The operation is simple and effective in properly selected cases. Care must be taken to exclude arthritis of the spine, tumors of the spinal cord or abnormalities of the spine. This means a complete set of *x*-rays of the lumbosacral region, a careful neurologic examination, and lumbar puncture in all cases.

By these tests all other conditions have been eliminated in this patient. His diagnosis, therefore, is sciatica due to con-

traction of the fascia lata. Division of the tight fascia will be done with excellent prospects of relieving his pain in this way.

**Case III.**—We have here a woman, forty years old, who formerly was employed as a stewardess on a steamer. Two years ago she began to have pain in the lower part of her back. She does not remember the onset definitely and can recall no injury. The pain increased in severity for several months until she was obliged to stop work. It was confined to the lower part of her back and did not radiate into her thighs. In September, 1935, she applied for

Fig. 132.—Case III. A 45 degree anteroposterior view of the lumbosacral joint. The last lumbar vertebra is transitional and is sacralized on one side.

treatment at the out-patient department of the New York Orthopedic Dispensary and Hospital.

She was a fairly well-developed woman, whose tonsils had been removed and whose teeth were in good repair. Her posture was fairly good. Motion was somewhat limited in all directions in the lumbar spine, apparently because of spasm of the muscles. There was tenderness over the lumbosacral but none over the sacro-iliac joints. Other tests were negative. x-Rays showed a transitional lumbosacral vertebra with incomplete sacralization on the right side. It was thought that this was the underlying cause of her back pain.

A corset, massage and exercises were prescribed and she was told that if her pain persisted after several months of this treatment, a lumbosacral spine

fusion would be advisable. At the end of three months she began to complain of pain in her fingers and left shoulder. There was tenderness over the lateral aspect of the shoulder and abduction and rotation were limited. There were slight swelling and stiffness of the proximal phalangeal joints of the fingers. From this it was apparent that she had a rheumatoid arthritis. Under appropriate treatment the symptoms in the joints improved and the pain in her back almost entirely disappeared.

This case is presented in order to emphasize the importance of considering arthritis as a cause of low back pain and also to show how difficult it may be, in early cases, to differentiate arthritis from some mechanical condition capable of producing the same symptoms. Here the appearance of the symptoms in other joints gave the clue. A careful search for foci of infection should be made in all cases and the history should include an interrogation about other symptoms indicative of arthritis. In doubtful cases a determination of the sedimentation rate may be helpful.

## CLINIC OF DR. LEO MAYER

### HOSPITAL FOR JOINT DISEASES

---

#### SCIATICA

SCIATICA is a somewhat vague term used to indicate pain associated with the distribution of the sciatic nerve. It is distinguished from sciatic neuritis in which actual organic changes in the nerve structure occur with consequent sensory and motor changes. These are absent in sciatica. Spinal cord tumors, herniations of the nucleus pulposus, bony irregularities of the vertebrae, may produce pressure against nerves composing the sciatic plexus and thus give rise to pain similar to that of sciatica, but these conditions are accompanied in almost all instances by objective neurologic phenomena such as changes in the reflexes and sensory disturbances. It is therefore important in any case of nerve pain referred to the sciatic distribution, to rule out neuritis, spinal cord tumors, and other extraneous causes of pressure against or irritation of the nerves of the sciatic plexus.

The term "sciatica," like its twin lumbago, has in the past been used as a cloak for ignorance. If the term is to be retained in good medical usage, and it is always difficult to drop a time-honored word, it should be used only in the same general way as the expressions headache or precordial pain, to indicate the distribution of pain and not as an exact diagnosis. For diagnostic purposes the term "sciatica" should be thrown into the limbo of discarded antiquities.

Sciatica is almost always due to a pathologic process in the sacro-iliac or lumbosacral joints and their associated ligaments. This process may be traumatic as in sprains of the ligaments and subluxations of the joints, or infectious as in arthritis, tuberculosis or actinomycosis, or metabolic as in gout. Rarely it may be neoplastic as in chordoma of the sacrum, sarcomata or metastatic carcinomata.

In reaching a diagnosis stress must be laid on an accurate history with particular reference to minor traumata such as strains occurring in putting on the shoes, getting out of bed or lifting a suitcase. In my own practice the larger percentage of cases are associated with an initial trauma. In eliciting a history, care should be taken to locate the distribution of the pain with accuracy. .

Although there is some difference of opinion between neurologists regarding the relationship between spinal segments and the sensory nerve supply of specific skin areas, there is in the main this agreement, that the anterior branches of the first, second and third lumbar nerves supply the anterior portion of the thigh; that the anterior branches of the fourth and fifth lumbar supply the anterior portion of the calf extending down to the big toe on the inner side of the foot; that the anterior branches of the first sacral supply the outer portion of the calf and the outer portion of the foot; that the anterior branch of the second sacral supplies the posterior portion of the thigh and calf. The posterior branches of the second, third and fourth lumbar, first and second sacral supply the region of the buttocks. Just why painful sensations should be felt in the leg without direct involvement of the nerves to these parts is still a subject for debate. It would seem probable that Head's explanation with regard to pain, holds true for the sciatic nerve distribution as well as for the visceral organs. Head states that when there is an irritation of a part of the body less richly supplied with sensory nerves than a corresponding skin area, irritations in the part of lower sensitivity are registered in that portion of the body with greater nerve sensitivity. In other words, if there is an inflammation of the ligaments of the sacroiliac joint normally supplied by a posterior branch of the second sacral nerve, the painful stimulus is felt chiefly in that portion of the buttock which is also supplied by the second sacral nerve. This theory is supported by the fact that in suitable cases of sciatica, injection of the strained ligaments with novocain causes the pain in the sciatic nerve distribution to disappear.

Since the pathologic process is usually in the lower back, the examination should be made so as to locate the exact site of the lesion. The following tests are of particular value:

1. Inspection of the patient in the standing position with the heels placed against a ruler, with the knees straight and the body relaxed. In a large number of patients a tilting of the body toward one side or the other will be noted, accompanied by a scoliosis, usually termed "sciatic scoliosis," and by a torsion either of the pelvis or the lumbar spine, or of the shoulder girdle, or all three portions of the body. Notation should be made of these variations from the normal. The patient is then asked to bend forward and limitations of the spinal motions noted together with the areas of pain which this act induces. Lateral bending and backward bending should also be performed with reference to the limitations of these motions and the pain induced by them. Bending tests should be made with the patient in the seated position, since frequently in cases of sacro-iliac strain, bending is decidedly freer when the hamstring group of muscles are relaxed by the seated position.

2. Palpation for areas of tenderness. Of particular importance are: (a) the sacro-iliac ligaments just below the posterior superior spine; (b) the sacrotuberous ligaments running from the sacrum down toward the tuberosity of the ischium; (c) the lumbosacral joints located about 1 inch from the midline in the angle between the ilium and the sacrum; (d) the points of emergence of the superior gluteal nerve just above the piriformis muscle lying between it and the superior margin of the sacrosciatic notch; (e) the crest of the ilium where the erector spinae muscles and the fascia of the back have their bony attachments; (f) the emergence of the sciatic nerve itself.

3. The straight leg-raising test known as the Lasègue phenomenon. In almost all instances of sciatica this test is positive. It is performed by gently flexing the thigh on the body with the knee completely extended. Normally the thigh can be flexed to an angle of 90 degrees. In a positive test this angle is decidedly nearer 180 degrees. Comparison of the two sides is of use in doubtful cases.

4. Gaenslen test. This is of especial value in determining whether there is any strain of the sacro-iliac ligaments. With the patient lying on the examining couch so that one buttock projects over the edge of the table, the thigh of this side is hyperextended while the opposite side is sharply flexed on the abdomen. This produces a torsion motion of the pelvis and

elicits pain in the hyperextended side of the pelvis if there is an involvement of that sacro-iliac joint. The test is repeated with the patient lying in the reverse direction.

5. The Ober test. This has recently been described by Dr. Ober and its significance is still of considerable debate. The patient is placed lying on his side, the thigh of the corresponding side is flexed to the maximum, the other thigh is then brought into complete extension, the ankle of this extended leg is supported by the examiner. In normal patients, the knee of this side will then drop toward the examining table. In a positive Ober test the thigh remains horizontal or in a position of slight abduction indicating a contracture of the fascia lata holding the thigh in an abducted position.

*x*-Ray examination should always be made. The following views are of value:

1. An *x*-ray picture of the pelvis and lumbar spine with the patient standing. The tube should be centered accurately on the symphysis pubis. This view will illustrate accurately deviations of the sacrum from the vertical position and accompanying scolioses. It will also show any abnormalities of the lumbosacral joints.

2. Lateral *x*-ray of the patient standing to indicate the relationship between the fifth lumbar and the sacrum with particular reference to slight displacements as well as to the occurrence of spondylolisthesis or forward slipping of the fifth lumbar on the sacrum or of the fourth lumbar on the fifth.

3. For accurate study of the joints, pictures should be taken in the recumbent position, not only in the anteroposterior and lateral views but also in the right and left oblique positions. The latter are of particular value in detecting fractures of the articular facets and arthritic changes in the intervertebral joints.

**Treatment.**—The treatment of sciatica must be directed to its cause. For this reason exact diagnosis of the pathologic lesion responsible for the sciatica is necessary for its rational treatment. In general, the treatment falls into two main groups: first, that directed toward the general disease responsible for the sciatica; second, treatment directed to the local cause. In the first group belong the cases of arthritis involving the lower lumbar vertebrae, the lumbosacral joints or the sacro-

iliac joints. Such cases require the same antiarthritic treatment as arthritis of the hip or knee. As in the case of the knee and hip, search must be made for foci of infection which in many instances are found in the gastro-intestinal tract rather than in diseased tonsils or apical abscess of the teeth. In addition to the general antiarthritic treatment, support must be given to the affected vertebrae. In mild cases this can be done either by a well-fitted corset, a spinal brace of the Knight type, or Goldthwait design, or by a plaster-of-paris support. In the more severe cases, the patients require rest in bed, preferably on a frame or in a plaster-of-paris shell.

The second large group of cases is the traumatic. In these the more precise the diagnosis, the more effective the treatment is likely to be. Particular credit should be given to Pitkin, of San Francisco, for his study of the sublaxations of the sacro-iliac and lumbosacral joints and for the methods of reduction which he employs to restore normal relationship. Pitkin has analyzed 1000 cases of traumatic low back pain associated with sciatica and has shown that in the majority, the type of lesion can be determined by exact analysis of the scoliosis and pelvic torsion. He has drawn diagrams illustrating the various patterns which may occur in a flexion or extension displacement of the sacrum on the ilium, in a forward or posterior displacement of the fifth lumbar on the sacrum. By reference to his charts, an accurate diagnosis can frequently be made. The maneuver which he has found most frequently successful to reduce these sublaxations consists in a forward rotation of the pelvis on the trunk combined with an upward push against the shoulder and a downward push against the pelvis. Naturally the rotation should be performed in such a direction as to overcome the particular sublaxation which is dealt with. Pitkin, as a rule, uses no anesthetic and applies only very gentle force. In cases associated with great pain he gives a low spinal anesthesia.

Until the Pitkin publications I had been accustomed to use more vigorous methods of manipulation. Those which have proved of particular value have been, first, the straight leg-knee extended, the thigh is forcibly flexed on the abdomen. Second, the external rotation abduction maneuver. In this the

thigh of the recumbent patient is abducted to 90 degrees, externally rotated and with the fist placed beneath the sacrum, the thigh is forced posteriorly thus tending to leverage the ilium into a forward position.

Third, the hyperextension maneuver. The patient is placed in the prone position, the thighs are hyperextended and as this is done, the sacrum is pressed forward. This maneuver tends to bring the ilium into a posterior position just as the preceding tended to bring it forward. Not infrequently the operator is compelled to attempt all of these maneuvers before he is able to overcome the displacement.

Following the reduction, firm adhesive plaster support should be applied to the lower back. By painting the skin with a solution of mastix or better still with "adherent" of Roth, irritation can usually be avoided. The adhesive straps should be 3 inches wide, and should run transversely from the level of the trochanters up to the first lumbar. Additional immobilization can be gained by including the lower abdomen in the strapping.

In severe cases the patient should be placed in bed. This phase of treatment cannot be stressed too strongly. Of all the measures used for sciatica, none is so important as rest on a firm mattress. If the spring of the bed sags, it is advisable to place boards between it and the mattress.

Physiotherapy has a place but should not be made into a fetish. To place the full responsibility for treatment of sciatica on the physiotherapist, however competent he may be, should be strongly condemned. Diathermy, sinusoidal stimulation, short-wave treatment, infra-red radiation, hot stupes, and gentle massage are all of value if given intelligently.

If analysis indicates that there is no subluxation but simply a strain of the ligaments, manipulation is contraindicated. In both groups when the strapping is removed, a support should be given which will reinforce the sacro-iliac and lumbosacral ligaments. In most cases a belt which gets its grip below the anterior superior spine of the ilium, is sufficient protection. If there is a strain of the lower lumbar spine, a more rigid type of apparatus is required. The Knight spinal brace is frequently effective; of particular value is the brace designed by Dr. Williams of Dallas, Texas. This ingenious device tends to hold

the lumbar spine in flexion thus taking the strain off of the lower lumbar spine and the lower sacro-iliac ligaments.

If, despite successful reduction of subluxations, rest in bed and effective support, sciatica persists, recourse must be had to extradural injections into the sacral canal. This procedure ought in my opinion always be performed in a hospital, not in the office or the home. The patient is placed in the prone position with the hips flexed. By careful observation the site of the sacral foramen just above the sacrococcygeal junction is determined. A few drops of novocain are infiltrated into this region, then with the spinal puncture needle the sacral canal is entered. Twenty-five cc. of 1 per cent novocain solution is injected and then 50 to 75 cc. of sterile saline solution. The injection must be done slowly. In successful cases the fluid should remain within the sacral canal, there should be no external swelling. Cadaver experiments show that fluid thus injected passes upward and outward along the roots of the lumbar and sacral plexus, infiltrating the nerves in this region.

In 1935 Ober, of Boston, published an operative procedure for the relief of sciatica. This consists in the division of the fascia lata in a line extending from the anterior superior spine to the tip of the greater trochanter. The rationale of this procedure has thus far not been discovered but in suitable cases the operation has caused complete relief of sciatic nerve pain. One of the difficulties in carrying out the Ober method is to determine in advance which cases are likely to react favorably.

Sometimes the Ober operation has a transient beneficial effect but the pain returns when the patients resume the upright position. This indicates the need for further analysis of the cause of the sciatica.

In those patients in whom, despite adhesive plaster support or other forms of bracing, the ligaments are so loose as to cause frequent recurrence of sciatica, operative measures must be used to fix the unstable joints. These fusion procedures are necessary in only a small proportion of the cases; in my own experience, in less than 5 per cent. The nature of the fusion depends upon the pathology. If the lesion is situated at the lumbosacral joint, the fourth and fifth lumbar should be fused to the sacrum. If one or both sacro-iliac joints are involved,

these joints should be fused. The technical details of the operation cannot be considered in this article.

**Prognosis.**—Despite inherent difficulties the great majority of cases of sciatica are curable. The incurable cases are those caused by malignant neoplasms, unusually severe arthritis or long-standing displacements associated with compensation neuroses.

## CLINIC OF DR. T. CAMPBELL THOMPSON

### HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### THE MANAGEMENT OF THE PAINFUL FOOT IN ARTHRITIS

THE complicated structure and the severe duties of the human foot render it peculiarly susceptible to anatomic, physiologic, and pathologic disorders. Only the vital organs have more constant or more difficult functions. Even a normal foot may give way if subjected to weight and strain disproportionate to its resistance, and a foot that is the site of localized arthritic manifestations, either active or quiescent, is rarely normal in structure, appearance, or function. Painful feet are often the chief complaint of the arthritic patient.

**Anatomy and Physiology.**—The study of any foot disorder should be based upon an intimate knowledge of the detailed anatomy of the foot, and a clear understanding of the various strains to which it is subjected in the unconscious effort of the individual to maintain the center of gravity over the weight-bearing area while standing, or to move the body weight forward from one foot to the other while walking. A detailed description of the various bones, ligaments, muscles, nerves, and blood vessels is not necessary here. Neither is it important to describe the arches and their functions, as the actual height of the longitudinal arch is of no importance.

While standing, the foot can be considered a pedestal upon which the body structure is balanced. When walking, it is a lever which acts to move the body weight forward. The weight-bearing area of the foot is roughly triangular in shape and normally the center of gravity of the body is balanced over it with practically no muscular effort. The weight is divided between the tuberosity of the os calcis and the metatarsal heads. The

head of the first metatarsal, through the two sesamoid bones beneath it, bears twice the weight of each of the others. The first and second together should bear as much as the three lateral metatarsal heads. In other words, the center of balance should fall in a line between the second and third toes. In walking, the projection of the center of gravity upon the ground moves forward along a line parallel to the long axis of the foot. This line is practically at right angles to the axis of the ankle joint. From the heel it bends laterally toward the fifth metatarsal head and then turns forward to go between the first and second toes. The weight-bearing area is then enlarged forward by flexion of the toes against the ground as the final "push off" is obtained by the first and second toes. Deformity, loss of flexibility, or pain will upset this entire foot mechanism.

**Foot Pain.**—The great majority of all foot pain can be traced to some anatomic abnormality, incorrect habit, or pathologic lesion which interferes with its normal function. Pain in the arthritic foot can be analyzed into that due to:

1. Localized pressure.
2. Ligamentous or muscular strain.
3. Local inflammation, acute or chronic.

Restoration and maintenance of normal function is usually accompanied by relief of pain.

**Pressure Pain.**—A large number of the common foot ailments can be traced directly or indirectly to excessive pressure. This pressure may be from a smooth shoe against certain irregularities of the foot, or from certain bones of the foot sustaining an undue amount of the body weight. With excessive standing or walking, or when the body weight is disproportionate to the size of the foot, the entire weight-bearing area may become inflamed and painful.

Any foot deformity which alters the shape of the weight-bearing surface, or changes the distribution of the body weight, will cause calluses beneath those bony structures which are thus subjected to excessive pressure. The skin of the foot itself is rarely sensitive, but plantar warts, though a virus infection, are prone to occur in weight-bearing areas and a minute plantar wart may be exquisitely painful. Ordinarily corns occur only at points subject to pressure of a shoe against a bony prominence. A soft corn, which occurs between the toes and

is acutely painful, can usually be traced to pressure of a small exostosis beneath it or upon the neighboring toe.

Calluses beneath any of the bones of the foot indicate poor weight distribution. These are found most commonly beneath the second, third, and fourth metatarsal heads due to spreading of the forefoot.

**Pain Due to Strain.**—Foot strain is probably the most common cause of pain in the feet and legs. This may occur in normal feet subjected to unusually long hours of work, or excessive loads. Pronated or weak feet, because of faulty mechanics, are especially apt to develop symptoms of strain. Insufficient circulation due to varicose veins, arterial or cardiac disease, may be a contributing factor. An arthritic patient, especially one who has been confined to bed for some time, is apt to suffer greatly from this type of pain when he gets back upon his feet, even though the arthritic process has altogether spared the lower extremities.

Changes in the structure and flexibility of the foot due to arthritis render it very susceptible to ordinary functional foot disorders. The correction of these static disorders in stiff, painful arthritic feet is a difficult task requiring the utmost patience and ingenuity.

**Pain Due to Inflammation.**—Patients suffering from arthritis are subject to numerous aches, pains, and tender points throughout the entire body, sometimes associated with true exacerbations of the disease, sometimes dependent upon weather changes, and sometimes without any obvious cause. Because of the constant strain of standing, and the trauma of walking, these symptoms, when they occur in the feet, are much more disabling than elsewhere. The swelling may not be visible but tenderness is usually acute. It may be found in or about one or more joints. It may be found along ligaments or tendon sheaths. It is often beneath a weight-bearing point such as one of the metatarsal heads, or the tuberosity of the os calcis, or it may be found in any of the bony or soft tissues without any apparent reason. One of the sesamoid bones, or the base of the fifth metatarsal, or the posterior tip of the os calcis may be the site of an epiphysitis during growing years. In adult life, arthritic pain seems to have an especial predilection for these points.

Certain types of arthritis seem to affect certain foot structures, but too much dependence cannot be placed upon this fact. Gout has an especial affinity for the first metatarsophalangeal joint. Gonorrhea produces painful bursae or spurs beneath the os calcis and may even make that bone sore and tender along both sides. Ordinary nonspecific chronic arthritis often produces a moderate or extreme stiffness of the tarsal and midtarsal joints with a marked tendency to clawing of the toes and prominence of the metatarsal heads. This claw toe tendency is probably due to the atrophy of the intrinsic muscles of the foot and may progress to partial or complete dorsal dislocation of one or more of the toes, with numerous painful corns and calluses.

**Pain Due to Inflammation and Strain.**—Periarticular or intra-articular inflammation in any joint results in pain, swelling, and limitation of motion. In most of the numerous joints of the foot the range of motion is normally small and its loss is of no great importance, but a painful lesion in or about any one of these joints will cause remarkable changes in the attitude and function of the foot as the patient subconsciously attempts to protect the affected area. Such a position, assumed during the acute stage, may become the habitual one if the arthritic process leaves any residual stiffness, a sequela which is all too common. As might be expected, those joints subjected to constant use are most apt to be affected. The joints along the medial side of the foot, constituting the longitudinal arch, are those subject to the greatest strain. The first metatarsophalangeal is perhaps the most overworked joint in the entire body and the frequency of hallux valgus, hallux rigidus, and ordinary exostoses show how often it is the site of arthritic changes. It would seem that the position assumed to protect those joints, which together form the longitudinal arch of the foot, would be a position of varus, throwing the weight on the outer or strong side of the foot. In fact if the foot is supported in this varus position with adhesive strapping, or plaster, considerable relief is often obtained and deformity prevented. However, because the strain placed upon the midpart of the foot is greatly increased during progression when it is used as a lever to raise the heel and thrust the body forward, this lever action is unconsciously avoided. The tendency is to evert and

abduct the foot using it only as a pedestal, in a flatfooted stumping manner with most of the weight borne on the heel. The great toe assumes a position of valgus to avoid the strain of a "push off" or the painful motion of dorsiflexion. This position of external rotation and pronation, originally adopted to relieve the affected tarsal and midtarsal joints during walking, soon becomes fixed. Consequently, even when standing, the center of gravity falls well to the inner side of the weight-bearing area producing strain along the medial side of the foot in the calcaneoscaphoid or "spring" ligament, along the inner side of the ankle, and even on the inner side of the knee. The thighs roll inward and the extreme flatfooted posture results.

**Examination.**—The examination must be systematic and complete. The history should note any foot symptoms present before or after the onset of arthritis. Weak or pronated feet are more apt to be the site of arthritic changes than normal ones. Arthritic foot pain can usually be differentiated from that due to ordinary foot strain. The latter type is directly related to the amount of standing and walking done by the patient, and is not usually troublesome at night or upon arising in the morning. Arthritic pain may come on at any time and is often affected by weather changes. Also there may be considerable stiffness which can be worked out by moderate activity.

The patient should be examined standing and walking, noting posture and gait, especially the alignment of the legs in respect to the weight-bearing areas of the feet. All deformities should be carefully noted and the range of motion measured in the ankle, subastragalar, midtarsal, and toe joints. Rarely are all the joints of the foot involved at one time and treatment should be directed toward those especially affected. The amount of pain associated with each motion is of more importance than the actual range. The entire foot and leg should be palpated for tender points and painful areas, and the presence of calluses, corns, plantar warts, or fixed toe deformities noted. Painful hallux rigidus, dorsal dislocation of the second toe, and localized tender areas in the sole of the foot can be easily overlooked. The circulation of the extremity may be judged by the color, temperature, and pulsation of the dorsalis pedis and posterior tibial arteries. The presence of

varicose veins or ulcers should be noted. Anteroposterior and lateral roentgenograms are usually indicated.

**Differential Diagnosis.**—Every effort should be made to evaluate all the symptoms and analyze the foot pain to determine whether it is due to pressure, strain, or inflammation, and whether alterations in the general or local circulation are contributory factors. The success of any treatment depends entirely upon the correctness of this analysis. Specific diseases which produce foot symptoms must be considered. Syphilis, diabetes, and arteriosclerosis frequently cause foot

Fig. 133.—Neglected arthritic feet. Equinovarus right. Equinocavovalgus left  
Fixed deformities of toes Glossy tender skin

pain. Bone tumors, tuberculosis, spurs of the os calcis, march foot, Freiberg's disease of the second metatarsal head, dislocations of the toes, and gout, can usually be demonstrated in roentgenograms or ruled out by appropriate laboratory examinations.

**Treatment.**—In the treatment of the arthritic foot the main objects are to relieve pain, prevent deformity, and if possible preserve motion. Simple methods of protection, support, and active exercise are of much greater value than all of the diverse medical and physical treatments which enjoy periodic popularity. If the probability of residual stiffness is

kept in mind, disabling deformities can be prevented. Ankylosis, if it occurs, need not be in a position which makes the foot useless as a weight-bearing organ (Figs. 133, 134).

In the acute and subacute stages rest is essential. Weight-bearing should be entirely forbidden and the foot should be supported in a neutral position. A firm pillow between the end of the bed and the soles of the feet, and a cradle over them to eliminate pressure of the bed clothes, may be sufficient to relieve pain and prevent foot drop. Carefully fitted and bivalved plasters can be prepared, but these should be removed daily to avoid undue stiffness. A simple posterior wire splint is a very satisfactory foot support to prevent equinus (Fig.

Fig. 134.—Claw toes and ankylosis with deformity caused by infectious arthritis.

135, 1). If there is a tendency toward claw toe deformity one can fit a special sandal with holes through the sole so that each affected toe may be strapped down against it (Fig. 135, 2). Compresses, local heat, baking, or diathermy often give considerable symptomatic relief. The prevention of foot deformities is much simpler than their correction and is of vital importance if the patient is ever to walk again.

As recovery progresses, nonweight-bearing exercises should be instituted before the patient attempts to stand. These are planned to restore mobility as much as possible and redevelop muscles which have usually undergone considerable atrophy. These exercises should systematically move all the joints of the foot and force all the muscles to function. Inversion and toe

flexion exercises are particularly important as eversion and claw toes are the deformities most apt to develop.

Fig. 135.—Methods of preventing deformity and relieving strain 1, Os-good posterior splint; 2, claw toe sandal; 3, inversion strapping; 4, pads for metatarsal or scaphoid regions; 5, sponge rubber for painful heels; 6, elastic metatarsal support, 7, metatarsal bar; 8, Thomas heel, 9, outside iron and T strap.

When the patient is allowed to stand, adhesive strapping for support and correction of pronation is usually very helpful

(Fig. 135, 3). Appropriate felt pads beneath the scaphoid bones or behind the metatarsal heads may be used to distribute the weight more evenly upon the sole of the foot (Fig. 135, 4). Elastic metatarsal straps with a metatarsal pad give welcome support and prevent spreading of the forefoot (Fig. 135, 6). Sponge rubber or dug-out heels are useful if the tuberosity of the os calcis is sensitive (Fig. 135, 5). A corn plaster or cut-out felt pad should be used to protect any painful bony prominence. If the metatarsal heads are tender, or the toes stiff and painful, a large metatarsal bar often gives great relief (Fig. 135, 7). Foot plates of various types can be fitted, but great care must be used in their design and they should be adjusted frequently. Molded leather supports are usually tolerated better than those made of metal. For a weak arthritic foot with pain in the scaphoid region or along the inner side of the leg, a well-wedged Thomas heel with an outside iron and an inside T strap is probably the best type of support (Fig. 135, 8, 9).

It must be understood that all of these conservative measures relieve sensitive and weak feet from pressure and strain, but cannot be expected to correct deformity. As the patient improves, exercises should be increasingly stressed, and when all signs of acute inflammation have subsided, motion can be encouraged by daily passive stretching of all the joints of the foot.

**Operative Treatment.**—Operative treatment should rarely be necessary unless conservative methods have been neglected. No operation should be attempted until the arthritic process is inactive. The safest and often the best way of correcting an arthritic deformity is by gentle stretching and application of plaster, repeated at short intervals. Stiffness is not overcome by this method, but, in the foot, a good weight-bearing position is more important than free motion. There is also the advantage that this stretching may be done even during the acute stage of the disease.

If gradual correction is not feasible or has failed, manipulation under an anesthetic may be indicated. To be effective, this must be followed by prolonged and careful supportive treatment and should never be attempted until some time after all acute symptoms have subsided. Although serious de-

formities may be corrected in this way, normal mobility is not usually regained.

Subcutaneous tenotomies of the extensor and flexor tendons of the toes and capsulotomies of the metatarsophalangeal joints will sometimes aid in the correction of deformed toes. Severe

Fig. 136.—The operative correction of arthritic feet

*A-3.* Hammer toe with painful corn.

*B-3.* Excision of corn. Fusion of interphalangeal joint (spiking operation)

*A-4.* Painful hammer toe with pressure on toenail.

*B-4.* Terminal Syme amputation removing toenail and distal phalanx

*A-5.* Claw toe projecting dorsally.

*B-5.* Excision of proximal phalanx

claw toe, especially if there is dorsal dislocation at the metatarsophalangeal joint, can often be completely and easily corrected by excising the entire proximal phalanx which usually projects upward. This "filleting" operation permits the remaining bones to drop plantarward and the toe to assume a

normal position (Fig. 136, 5). The period of convalescence is very short and no immobilization is necessary.

Hammer toe may be corrected by excision of the corn and arthrodesis of the deformed joint (Fig. 136, 3). However, it is often advisable to remove enough bone to allow free motion, as arthrodesis in good position requires very prolonged and careful splinting and adds one more stiff joint to an already too rigid foot. In most operations upon the forefoot one should remove bone freely and soft tissue sparingly or not at all.

Any metatarsal head which becomes too prominent and bears an undue portion of the body weight should be cleanly excised through a dorsal incision, allowing the weight to be distributed equally to the other metatarsal heads (Fig. 136, 2).

Corns and calluses require continued protection against pressure, or an operation correcting the bony abnormality which causes the pressure (Fig. 136, 3).

A painful deformity of the distal phalanx of a toe with pressure upon the nail may be easily corrected by a terminal Syme amputation removing the nail and distal phalanx (Fig. 136, 4).

Hallux valgus and hallux rigidus are very common in arthritic feet. Removal of the exostoses from the metatarsal head and excision of the proximal one half of the proximal phalanx usually corrects the deformity. The sesamoid bones and the weight-bearing area of the first metatarsal head should be avoided if possible, and an hour-glass constriction formed between the metatarsal head and the remainder of the phalanx to insure free mobility (Fig. 136, 1).

Amputation of one or even all the toes may be indicated if deformities are severe and the feet very painful.

Equinus, cavus, varus, and valgus deformities may require subastragalar, midtarsal, or even ankle arthrodesis with the removal of appropriate bone wedges. The foot should be re-aligned beneath the leg with a large smooth weight-bearing surface in contact with the ground. Painful motion should be eliminated from weight-bearing joints by arthrodesis, and from nonweight-bearing joints by wide excision.

Although there are numerous problems in the treatment of arthritis which defy solution, the prevention or correction of the painful foot deformities can be accomplished.

## CLINIC OF DR. CORNELIUS H. TRAEGER

### HOSPITAL FOR THE RUPTURED AND CRIPPLED

---

#### FIBROSITIS

IN the arthritis clinic of the Hospital for the Ruptured and Crippled, New York City, we have had 900 admissions in the past two years. In a careful chart analysis of these cases we find a total of 262 patients who have as their presenting symptom pain in or about the joints with no external evidences of joint pathology such as swelling, redness, fluid, muscular atrophy or deformity. On roentgenologic examination of the joints involved we find no evidence of bony pathology. Yet these patients are truly ill. They have severe pain, frequently severe enough to prevent them from working or obtaining proper sleep; they have stiffness and disability. Of this group of 262 patients, 128 gave a history of having their complaint less than two years. One hundred and thirty-four dated the onset of their illness from two to eighteen years prior to admission. It is to be remembered that these patients were admitted to an arthritis clinic and yet they presented complaints which could not be segregated into the broad grouping of rheumatoid, osteo- or mixed arthritis. It is a fair assumption that if we were dealing with arthritis in these 134 cases of over two years' duration, some bony change would be apparent either grossly or roentgenologically. These patients showed no great variations from the normal blood chemistry values, blood counts or sedimentation rate. The paucity of abnormal laboratory or physical signs established these patients in a segregated group and for want of a better term we shall consider them as cases of fibrositis. Of all the entities grouped under the general heading of rheumatoid disease, fibrositis presents the most perplexity. There are some physicians who deny that fibrositis is

a clinical entity; others claim it the most important and the most widespread of all the rheumatoid diseases.

Much confusion attends the etiology, pathogenesis and classification of fibrositis. In a discussion on fibrositis last year Dr. Philip Hench made the following remarks: "If gout in America is a forgotten disease, fibrositis is an unknown disease, at least it is not known by that name. The disease is very widespread both in England and America, but very little is written about it in this country and the term fibrositis is practically unrecognized here."

Fibrositis, as the term indicates, is an inflammatory reaction of the fibrous tissue of the body. The term is well chosen and is based on the pathology of the disease. Frequently fibrositis is incorrectly used interchangeably with myositis but true myositis is uncommon. We are of course not including such diseases as myositis ossificans, tropical myositis, gonorrheal or syphilitic myositis or progressive myositis fibrosa or acute suppurative myositis. What the general practitioner terms as myositis or muscular rheumatism is in reality an involvement of the interstitial muscle tissue rather than the muscle parenchyma.

Fibrositis is a disease which is just as important as any other of the rheumatoid group. Patients with this ailment suffer just as acutely, are just as disabled, present the same financial problem as do those suffering with any of the other arthritides. It is important that our concept of fibrositis be clarified since so many of these patients are labeled as arthritics, with all the dread which such a diagnosis produces in their minds. So frequently doctors are prone to label these patients neurotics or psychotics because they cannot find any external evidence of pathology in the joints and no laboratory tests to support any other diagnosis.

This disease was originally described by Jaccoud as "rhumatisme chronique fibreux." Its present usage dates from the introduction of the term by Gowers in 1904 and by Stockman in 1933 and 1934. Fibrositis may be roughly classified into 3 groups: (1) primary fibrositis, the type which is the subject of discussion in this paper, which is an affection of fibrous tissue independent of pathology elsewhere in the body; (2) symptomatic or secondary fibrositis in which the changes in the interstitial tissues are secondary to some more deep-seated

lesions such as rheumatoid arthritis, spondylitis, rheumatic fever, gonorrheal arthritis, trauma, etc., and (3) senile fibrositis, representing the gradual fibrotic changes which take place in the later decades of life.

Fibrous tissue exists everywhere in the body and since it is subject to inflammatory reactions wherever situated, the anatomic distribution of the disease is of course widespread and it may be classified according to location.

First—panniculitis, that is, a fibrositis of the subcutaneous tissue which includes the areolar and adipose tissue. It is characterized by a loss of elasticity of the skin, which seems to be more adherent to the underlying tissue. Patients complain of a sense of chilliness and a diminution of sense of touch. Panniculitis is frequently painful. It is usually localized in the thighs or the back of the neck and occasionally it has a more widespread distribution. The most severe types of headache accompany cervical fibrositis. Telling considered it the most frequently found type of chronic or intermittent headache, the four diagnostic features of which are persistency, thickening, nape of the neck location and tenderness. The most intense headache I ever encountered was due to cervical fibrositis. This patient had been treated for sinusitis, had had several pairs of glasses made and had a complete neurologic survey, all without avail. She had resorted to narcotics in a desperate attempt to obtain some surcease from her suffering. The pain was limited to the occipital region associated with definite tenderness. Simple physiotherapy relieved her of all symptoms. When fibrositis involves the chest muscles it gives rise to the condition known as "pleurodynia" or intercostal fibrositis, which can be extremely painful and persistent and when confined to the left side of the chest is not uncommonly diagnosed as angina pectoris, or when bilateral is frequently mistaken for pleurisy. The chest is frequently tender and respiratory excursions limited. Breath and voice sounds are normal, friction rubs and râles are absent. Pain is increased with coughing, breathing or sneezing. Abdominal fibrositis is characterized by pain and tenderness elicited by "fingertip pressure," tender spots are frequently localized but may be multiple and occupy positions which are not usually affected by underlying visceral disease. Muscle spasm or rigidity, which is characteristic of

abdominal disease, is usually absent in fibrositis and the pain, which is constant in abdominal disease, is intermittent in fibrositis.

Second—intramuscular fibrositis (myositis or muscular rheumatism). In this group we must also include the inflammatory reactions in the fascial planes as well as the interstitial tissue of the muscle. It must be kept in mind that the parenchyma of the muscle is not involved but only the interstitial tissue. Intramuscular fibrositis may be localized or diffuse. This condition is frequently termed myalgia, neuromuscular pain, muscular rheumatism or myofascitis, and is characterized by pain on extremes of motion or intermittent subjective pain and muscle stiffness (jelling phenomenon). The pain may be persistent as in lumbago, may come on only with exercise or following strenuous work or may be intermittent. The pain here is localized, not at the joints but between them. Limitation of movement, if any exists, is produced solely by muscular stiffness rather than by pain or joint pathology.

Third—periarticular fibrositis which involves the joint capsule. This type of fibrositis is characterized by stiffness and soreness of the joints particularly after long periods of rest or on arising in the morning. Pain may also be elicited by abnormal stretching of the capsule. Tenderness is usually absent or fleeting in character. These symptoms are frequently transient in nature but occasionally persist.

Fourth—bursal fibrositis or bursitis. Bursal fibrositis is quite common and is to be distinguished from bursitis which is accompanied by increase of fluid in the bursal sac. In bursal fibrositis there is not the definite limitation of motion characteristic of true bursitis. Pain is only present on extremes of motion and tenderness is frequently absent. Calcification of the bursa is absent.

Fifth—tendinous fibrositis, or tendinitis, is a condition which involves the fibrous tissue of the tendons, is uncommon and more frequently found as Dupuytren's contracture.

Sixth—perineural fibrositis or interstitial neuritis is frequently called neuritis which is a misnomer. This generally affects the large nerves such as the brachial plexus and sciatic nerve. Sciatic fibrositis should be distinguished from a true sciatic neuritis. The fibrositic forms may be distinguished

from sciatica because in the former the pain is referred to the hamstring muscles and not the nerve trunk. In perineural fibrositis the pain follows the nerve distribution. There is no anesthesia or paresthesia over the area of distribution of the nerves. The pain of sciatic fibrositis is less severe and is confined to the muscles and is characterized by local soreness, tenseness and muscular stiffness. In brachial fibrositis there is tenderness over the brachial plexus above and below the clavicle and pain is elicited only with abduction of the arm.

**Etiology.**—The etiology is of course unknown. In the analysis of our 262 patients we find that the disease has frequently followed chill, fatigue, trauma or chronic strain, infection, nervous exhaustion and very frequently follows influenza or respiratory infection. Focal infections were frequently found in many of these patients. Some authors stress the importance of chilling or climatic change. Others emphasize the importance of focal infection, metabolic disorders, intestinal toxemia and allergy. There is as much confusion with respect to the etiology of fibrositis as there is in chronic arthritis. It is quite possible that any or all of these factors may act as etiologic or precipitating factors in the production of this disease.

**Pathology.**—Here again we are beset with many difficulties for the simple reason that patients object strenuously to biopsies. Slocumb describes the pathology as follows: "In stage one there is an inflammatory serofibrinous exudate of low grade with proliferating fibrositis and newly formed blood vessels. In stage two, if the inflammatory process is more severe and of longer duration, indurated, local, tender, thickened tissue or frank, gross, subcutaneous nodules may be produced. They may become firm and in them may be found dense inflammatory hyperplasia of fibrous tissue, thickened blood vessels and inflamed nerve fibrils. There is no leukocytic reaction. In stage three, when the inflammatory activity has passed spontaneously, or as the result of treatment, some indurations may disappear. Others remain as painless thickenings or nodules. Fibrous, tendinous contractures, capsular thickenings may affect such joints as the shoulders and palms."

Most writers stress the importance of the fibrositic nodule. In our group of patients these fibrositic nodules were con-

spicuous by their relative infrequency. When present they were usually very deep-seated and would have presented difficulties for their surgical removal. A more frequent finding was a generalized solidness or spasticity of the muscles involved. The fibrositic nodules vary in size from a "pea" to an "almond," and are not to be confused with the subcutaneous nodules found in rheumatoid arthritis. Cyriax believed that these nodules were produced by small localized muscular contrac-

### DIFFERENTIAL DIAGNOSIS

#### *Fibrositis*

Limited to a definite area.  
Tenderness is a variable factor.

Stiffness present or "jelling phenomenon" which disappears very quickly after exercise or movement. Very frequently the first symptom which the patient with fibrositis complains of is this "jelling" or stiffness of the joints after long periods of rest, such as sitting in a theater seat, playing bridge or on arising in the morning.

Muscular atrophy rare.  
Synovial exudate never found.  
Pain elicited only on extremes of motion, or any type of forced movement which produces tension of the capsule.

Pain frequently relieved after moderate exercise.

Frequent remissions.

Systemic manifestations are uncommon.

Capsular thickening may be present.  
High sedimentation rate and secondary anemia rare.

No roentgenologic evidence of bony involvement.

#### *Rheumatoid Arthritis*

The rule is polyarticular involvement.  
Tenderness frequently outstanding symptom.

Stiffness persists after motion or exercise.

Muscular atrophy quite common.  
Synovial exudate a frequent finding.  
Pain on motion of affected joint characteristic symptom.

Painful following exercise.

Remissions uncommon.

Systemic disease frequently attended by slight rise of temperature, loss of weight and appetite, secondary anemia and low blood pressure

Capsular thickening may be present  
High sedimentation rate and secondary anemia frequent occurrence  
Roentgenologic evidence of bony pathology is the rule

tions and that when nodules rapidly disappear under various measures, it is the muscular contraction that disappears, leav-

ing a residual nodule too small to palpate. The importance of these fibrositic nodules is still undetermined and until more of these nodules and their adjacent tissue in various stages of the progression of the disease are examined, our judgment should be reserved.

**Prognosis.**—The prognosis of fibrositis is good. It is the most tractable of all the rheumatic affections. Where the onset is acute, rapid cure is the rule. In the more chronic cases careful treatment must of necessity be persisted in for longer periods of time. The prognosis of course depends on the etiologic factors encountered and on the general condition of the patient. Favorable results can only be obtained by the careful elimination of etiologic factors and persistence in using all the available methods of treatment.

**Treatment.**—The treatment of course divides itself into two main groups, general and local. Rest is important in the relief of pain but should be confined only to the acute stage of the disease. Exercise should be gradually instituted. Patients suffering from fibrositis are affected by change of weather and it sometimes becomes important to change the climatic surroundings of such patients. Cold and dampness militate against recovery and a change to warmer, more pleasant surroundings is frequently advisable. Many of the cases of "arthritis" who are cured by trips to Florida or Arizona were probably not arthritis at all but really fibrositis. The complete change of environment is sometimes helpful in relieving the patient of the stress and strain of his everyday existence. Drugs are only of importance in the relief of pain and salicylates are most frequently employed and should be administered in adequate doses.

Many writers stress the importance of vaccines in the treatment of fibrositis. Scott extols the virtues of a lipovaccine injected into the fibrositic area. May states that the best results are obtained by a combination of vaccine treatment with physical therapy. Vaccines in this connection are not used for their specific effect but more for their nonspecific protein effect. A stock vaccine of the mixed streptococcus type is the one most frequently employed.

The question of the importance of diet is still in dispute. Some writers think it of great importance, others think it plays

no rôle in the treatment of this disease. A well-balanced diet which provides for proper vitamin intake and regulated with respect to the patient's body habitus is to be recommended.

*Gastro-intestinal Treatment.*—Albee stresses the importance of intestinal toxemia as an etiologic factor in fibrositis and strongly recommends the use of colonic irrigations. May states that he is convinced that the most common cause of toxemia producing fibrositis comes from the gastro-intestinal tract. Where intestinal stasis or intestinal toxemia is present colonic irrigations have proved to be useful adjunctive therapy.

Foci of infection when present should be removed if the patient's condition warrants it. Spectacular results have been observed following the removal of obviously infected teeth or tonsils or by proper treatment of involved sinuses. Hunt reports 2 cases of fibrositis with *Bacillus coli* infection in the genito-urinary tract who recovered only when the urine became sterile. Focal infections in the appendix, gallbladder, cervix, tubes or prostate are considered to be less commonly involved although their importance is stressed by various writers.

*General Physical Therapy.*—Where fibrositis is more or less generalized, cabinet baths prove useful. Hot Epsom salt baths are frequently recommended. General massage is important only in the stimulation of the general vasomotor system and the lymphatic circulation of the body.

*Local Measures.*—There are many forms of local therapy and all of them are important. To rely on any one particular method of treatment invites failure. The object of course is to relieve pain and to stimulate the absorption of the infiltration. The most frequently used method is diathermy; ultra-short-wave and the conventional diathermy are the generally accepted methods. These frequently increase the subjective pain temporarily but will usually bring about improvement. Histamine ionization, which is the use of galvanic current for the introduction of drugs into the tissues, is said to be of more value in the acute stages of this disease than in the chronic stages. MacKenna claims it can completely cure the condition. Infra-red radiation, especially to the smaller joints, is an excellent mode of therapy. Hydrotherapy is another excellent adjunct to treatment and may be utilized in various

forms, either total immersion in specially prepared tanks, or pools filled with warm water or whirlpool baths or just hot soaks, have proved efficacious. Contrast baths or Scotch douches have also proved useful. Paraffin baths for the extremities frequently produce excellent results. In the procedure the arm or leg is immersed in molten paraffin at temperatures between 110° and 120° F. several times until a glovelike coating is produced. The extremity is then wrapped in a towel for twenty minutes, following which the paraffin is peeled off and gentle massage instituted. Use of the static current has fallen into disfavor and is seldom used in the treatment of fibrositis.

The most important of the local measures is of course massage. This should be done gently at first, followed by more vigorous massage as treatment progresses. It is important that the movement of the joints be maintained by passive motion from the onset. Vigorous massage will eliminate the muscle stiffness and frequently cause the disappearance of the fibrositic nodules. Such treatment will of course be painful and if the patient finds it difficult to relax his muscles sufficiently because of the pain, analgesics should be employed prior to the treatment and the preliminary baking should be prolonged. Massage, of course, should always be preceded by heat applied in some form. Massage never should be used in the acute phase. Heat should be applied without massage during the stage of effusion.

**Conclusions.**—Fibrositis is a definite clinical entity, little understood or appreciated in this country. It is of frequent occurrence and is important from the standpoint of pain, disability and financial loss to the patient.

Etiologic factors are usually chill, trauma, fatigue and infection.

Pathology is represented by inflammatory infiltration of the interstitial tissues of the body.

The various types of clinical manifestations of fibrositis are described in detail.

The differential diagnosis is described in detail.

The disease is characterized by paucity of abnormal laboratory or roentgenologic data.

Treatment is divided into general and local therapy, a detailed description of which is found in the text.

The prognosis is good.

## CLINIC OF DR. MARTIN HENRY DAWSON

THE EDWARD DANIELS FAULKNER ARTHRITIS CLINIC, PRES-  
BYTERIAN HOSPITAL

### A NOTE ON THE OCCURRENCE OF PSORIASIS IN RHEUMATOID ARTHRITIS\*

THE association of psoriasis with chronic arthritis has long been a matter of clinical observation, especially among members of the French school of medicine. According to Garrod and Evans, Alibert, in 1822, was the first to recognize the occurrence of joint pains in psoriasis and since his time many observers have commented on the occurrence of these apparently diverse disease processes in the same patient. One variety of this symptom-complex has occasioned particular interest and has been designated by various terms such as *psoriasis arthropathica*, *arthropathia psoriatica*, *psoriasis arthritica* or *psoriatic arthritis*. By these terms there is generally understood a more or less severe form of chronic arthritis of the rheumatoid type associated with extensive psoriatic lesions. Many authors insist that these terms be restricted to cases exhibiting the following features:

1. The psoriatic lesions are atypical in character and distribution. The eruption is exudative in nature, associated with waxy, translucent papules and large abundant scales. The hands and feet are frequently affected and there is a marked tendency for the process to involve the nails.
2. The onset of the psoriasis may precede, or coincide with, the onset of the arthritis but exacerbations of the one are usually accompanied by exacerbations and remissions of the other.

\* From the Department of Medicine, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital.

3. The arthritis is characteristically rheumatoid in type with the curious exception that the *terminal* interphalangeal joints of the hands and feet are frequently affected.

Other observers believe that the term *psoriasis arthropathica* should not be so narrowly restricted and that it should include all cases of psoriasis and rheumatoid arthritis. There is general agreement that the association of psoriasis with osteo- (degenerative) arthritis is a pure chance phenomenon.

We have had the opportunity of studying 19 cases of rheumatoid arthritis in whom psoriatic lesions were present. Seven of these cases conformed to the requirements of *psoriasis arthropathica* in the narrower definition of the term. In 7 others the psoriasis showed the atypical, exudative type of lesion but the arthritis was of the classical, rheumatoid variety. In the remaining 5 cases neither the psoriasis nor the arthritis showed any unusual features.

Our observations lead us to question the advisability of restricting the term *psoriasis arthropathica*, or its synonyms, to those cases which show atypical manifestations of both diseases. It appears that a certain number of cases of rheumatoid arthritis develop psoriasis (actually less than 2 per cent) and that a certain number of psoriatics develop rheumatoid arthritis. The occurrence of these two disease processes in one and the same patient is an interesting phenomenon and merits further study.

### MASSAGE AND EXERCISES IN ARTHRITIS

MANY attempts have been made to find a specific remedy for arthritis. All of them have failed, as could be expected, because arthritis is not due to one etiology. However, in the control of arthritis we have certain principles that have been tried out for centuries, and are still used, while other remedies come and go. Wherever arthritis is treated, massage and exercises have always occupied an important part in management of the arthritic patient. It is being used empirically by many, although we know fairly accurately the indications and the contraindications. Sir Robert Jones has said that the value of massage is too well established to require defense. Yet it cannot be denied that many of the ideas prevalent as to its methods of use are often vague, and doctors who have made a close enough study of the subject to give definite directions to a technician are still fewer than they should be. The main physiologic actions of massage should be known to the doctor, although the actual practice of it must be left to properly trained technicians. The physiology of massage may be briefly reviewed under *mechanical action* and *reflex action*; only the former concerns us here. We may consider the mechanical action under three headings:

1. Assistance to circulation of blood and lymph. The unit of our body is the cell and the cell metabolism determines our body metabolism. The absorption into the cell of carbohydrates, fat and proteins and oxygen, and the discharge of residues of the cell metabolism can be activated by massage; this can fill and empty the capillaries. The capillaries are often contracted and tortuous in arthritis. The stroking along the veins will help empty these and accelerate the blood flow

through the capillaries. The same massage will help the return of lymph and prevent or relieve stasis. The mechanical action of massage on circulation is a pressure-suction action which helps the vasomotor system, and restores the proper balance in the cells.

2. Massage helps to break up and absorb adhesions. If India ink is injected into the knee joints of a rabbit, and only one joint is massaged, we will find that the India ink will be absorbed readily in the joint which is massaged, while it will remain in the other joint. The invasion of a joint by arthritis will show congestion, productive inflammation, and connective tissue proliferation both in the joint and around it, resulting in a stiff joint. Massage will help to restore such a joint to normal after the acute onset.

3. By alternating pressure and release we can restore the tone of muscular tissue, and the hollow viscera. This manipulation of skeletal muscle is well known, but the abdominal massage is not utilized as it should be. It is especially beneficial in bedridden patients.

The technic of massage can be reviewed under stroking or effleurage, kneading or petrissage, and hacking or tapotement.

*The effleurage* is a stroking movement of the palm of the hand sliding over the patient. We speak of superficial and deep stroking. The difference is in the force applied. The superficial stroking should be light, rhythmical, and unidirectional, following the venous flow; the actual stroke should be of the same length as the return stroke. *Effleurage* is used for the mechanical effect on the circulation.

*The kneading* is done by the palmar surfaces of the hands, the heel of the hand, the thenar eminence, all the fingers or the thumb alone. The soft tissue is kneaded by circular motions. This hand movement is used to restore the normal balance of the soft tissue, and to help absorption.

*Tapotement* is any hacking, beating, or clapping with the palmar surface of the hand, the ulnar surface of the fingers or hand, and by a loosely held fist. The main effect is stimulation to the muscular tissue, and the nervous tissue. The well-trained technician will know how to combine these hand movements in individual treatment, the same as an artist blends his colors.

We may set certain rules for the patient undergoing massage. He should always lie down, undressed, well supported and relaxed. Massage should not be given when the circulation is needed to take care of the digestion. Stimulative treatments should be given in the forenoon, recuperative or sedative treatments in the afternoon or evening. The skin of the patient should be clean and warm.

The rules for the technician include cleanliness and neatness in appearance. The hands should be warm and dry. Intelligence is more important than strength. Exercises are usually included in the treatment, so that the technician should be well trained in exercises as well as massage. I am in a position to meet more technicians than probably any one in the country, and it is a sad reflection on the credulity of the medical profession to read their letters of recommendation for masseurs who have the most inferior training, or no training at all.

Massage is often associated with various medications, which have been credited with beneficial action in arthritis. However, any absorption of medication through the skin is questionable. What is needed, therefore, is only a lubricant. These are of two main groups, the fatty acid and the powder. Most of our ointments are in the fatty acid group. These should be used on dry, hairless skin, and for local treatments. The powder, such as talcum, should be used on moist or hairy skin, and for general treatments. Both ointments and powders can be scented with volatile oils, but these are of olfactory benefit rather than therapeutic value.

In the typical patient with rheumatoid arthritis, we deal usually with an individual who is below par generally; has poor muscular tone and atrophy. The treatment should therefore be directed toward a general building up; the massage should be concentrated on the soft tissue, especially the muscles, and the joints should be avoided. This is paramount in the bedridden patient with acute arthritis. The massage should be light. We should avoid tiring the patient. In subacute and chronic cases the massage can be used on the joints. We are often confronted with unbalanced muscle groups as part of the picture of beginning contracture and deformity. In such unbalanced muscle groups, stimulating massage should be used

on the elongated muscles and relaxing massage on the shortened muscles.

In osteo-arthritis the patient is often overweight, and general massage is given to counteract the inactivity. The local massage can be given directly to the joint, and can be more vigorous than that given in rheumatoid arthritis.

Osteo-arthritis so commonly involving the fingers can be successfully treated with paraffin dips preceding massage. Ordinary laboratory paraffin is used, which melts at 150° F. Let it cool to 130° F., then have the patient dip his hands into the paraffin a dozen times, cover them with a towel for fifteen minutes, then massage each finger individually. This preparation for massage by paraffin can be used on any joint of the body, and when dipping is not feasible we apply it by means of a brush. Preliminary heat for the whole body, however, is best done by a heat tent, *i. e.*, a tent made of a sheet, containing a lamp, is arranged over the patient.

The prescription of massage in the management of the arthritic patient should be for a specific purpose. It should state whether general massage is desired as a tonic for the patient, or as a remedy for inactivity. If local massage is indicated for an atrophied muscle group or to promote absorption in a given joint, I believe that better results could be obtained if the doctors were more discriminating in their prescription of massage in the management of the arthritic patient.

#### EXERCISES IN ARTHRITIS

The symptoms that will bring most arthritic patients to seek medical advice are pain and stiffness. The pain is usually associated with motion in a damaged joint; this will result in stiffness, later deformity. The question of rest versus exercises in the treatment of arthritis has always been difficult to answer. It is evident that we must rest an acute arthritic joint, but when should the rest stop and movements be started? In a general way I believe that it is safe to say that the sensation of pain is given us for a protective purpose, and therefore anything producing pain should be contraindicated. However, this must be modified, or half the human race would go to bed and remain there. The painful sensation from the joint surface

itself can be used as a criterion for activity in a joint, but the stiffness from the muscles, ligaments, and capsule should be differentiated from true joint pain.

We may simplify the discussion of exercises if we consider them under these three headings:

1. Body mechanics reconstruction.
2. Local active exercises.
3. Passive manipulations.

**Body Mechanics Reconstruction.**—It is impossible to classify arthritis into definite groups, but we are all conscious of certain types which we recognize as the rheumatoid or osteoarthritic variation. These types are not inclusive, nor are they always pure. However, they do serve to direct our attention to arthritis as a disease not of the joints alone, but as a widespread disorder of the whole body machine.

Body mechanics is the function of all the parts that make up the human body. It deals with the skeleton, the muscular system, the nervous, gastro-intestinal, circulatory, respiratory, renal and endocrine systems. When we study the arthritic patient from the point of view of body mechanics, we may easily differentiate between the rheumatoid type and the osteoarthritic type.

*Rheumatoid arthritis* is usually found in the slender anatomic type of person between the ages of twenty and forty. The body as a whole sags. The head sags, the back, the chest, the shoulders, abdomen, knees and feet all sag. This outside appearance of failure corresponds to the actual failure of the body to do its work as shown by underweight, weakness and muscular atrophy, low vital capacity, and low basal metabolism. The inefficiency of the circulation shows itself in low blood pressure, secondary anemia and subnormal temperature. It is evident that the organs and viscera responsible for these functions are working under great disadvantage, and the body as a whole presents a decreased resistance to invading micro-organisms.

The correction of such faulty body mechanics presents a rather complex problem. We must align the skeleton in its proper interrelation. The head must be so balanced on the cervical spine that the respiration is unobstructed, the circulation to the head is free and there is no sagging of the cervical

fascia which helps to support the diaphragm and the abdominal viscera. This is done by carrying the chin in. The spine will show either an increase or decrease in the normal curves, and this should be readjusted by postural instruction in having the patient maintain the corrected alignment for longer and longer periods until it becomes no effort at all. The shoulders should be carried low and the thorax high. A very important point in the skeletal correction is the pivot point between the spine and pelvis. The lumbosacral angle is often increased, tilting the pelvis forward, thereby straining the ligaments in the lumbar region and permitting the viscera to spill over the brim of the pelvis pressing against the lower abdominal muscles. Here we should attempt to bring the sacrum under the fifth lumbar vertebrae in good weight-bearing position.

If a line is drawn from the mastoid process, the acromial process, through the greater trochanter and external malleolus in the standing position, this line should be straight. When a plumb line falls through the middle of the patella and the second toe, we have the proper weight bearing on the lower extremities. To maintain this proper weight bearing on the feet is most important in order to prevent damage to cartilages of feet and knees, hips and lower spine.

The skeleton is dependent on the muscular support. In normal conditions there is a perfect balance between the antagonistic muscle groups. The head is balanced by the neck muscles which act as guy ropes; the shoulder girdle is balanced in the horizontal plane by the pectoral and the trapezius muscles; the lumbosacral angle is maintained by the abdominal muscles and rectus femoris in front, and the gluteus maximus and hamstrings in back. We find the same muscle balance between the quadriceps and hamstrings responsible for the control of the knee. In the foot we must have balance between the flexors and the extensors, the invertors and evertors in order to maintain the proper weight bearing and locomotion. When this balance is disturbed we set up abnormal stress, strain and pressure on the corresponding joint cartilages and ligaments. This sets the stage for an arthritic invasion of the joints.

The heart and the diaphragm are of great importance in the analysis of body mechanics. The function of the diaphragm is not only a respiratory one, it also has a definite effect on the

thoracic and abdominal veins. The lengthening and shortening of the veins attached to the diaphragm is important in the pumping of the venous circulation. The position and the excursion of the diaphragm can be analyzed by x-ray or fluoroscopic examinations. By diaphragmatic exercises we can improve the excursion of the diaphragm and secondarily help the circulation.

A vital capacity study of patients with rheumatoid arthritis showed a persistent low percentage of normal. The average vital capacity in a group of 50 patients was about 25 per cent less than normal. This vital capacity was calculated from the height and weight, which gives the body surface. This body surface with spirometer readings gives you the vital capacity of the lungs. This low vital capacity is what you might expect in the dropped chest. This sagging of the thorax is important because it serves as muscle attachment of the respiratory muscles. These muscle attachments are brought closer together, thus making their function mechanically less efficient. This is especially true of the diaphragm. Respiratory exercises therefore are essential in the reconstruction of poor body mechanics as related to rheumatoid arthritis.

The abdominal viscera and the pelvic organs vary considerably in their position, but we must recognize certain limits to the displacement. A stomach above the umbilicus undoubtedly functions better than one in the pelvis. The sagging of the abdominal viscera is usually compensated, but the uncompensated visceroptosis is followed by malfunction and congestion. This will add to the poor health of this type which is so often a victim of rheumatoid arthritis. We must counteract the tendency to visceroptosis by increasing the tone of the abdominals with exercises. Abdominal exercises complete the picture of the reconstruction of poor body mechanics.

*Osteo-arthritis* is more common in the heavy-set individual with a tendency to overweight, high blood pressure, and good muscular development. He starts with good body mechanics and acquires visceroptosis and poor posture. It is more common in people over forty. The arthritic changes are found in the joints which are subjected to weight bearing and mechanical stress and strain. Faulty body mechanics in conjunction with poor metabolic chemistry is the cause of osteo-arthritis, rather

than infection. Exercises in the management of osteo-arthritis are based on a correction of faulty body mechanics and in addition general exercises for the maintenance of muscular tone and the reduction of weight. This type of patient should be kept active and especially encouraged in exercises without complete weight bearing such as swimming, horseback riding, etc.

From this very brief review of types of arthritis, we might suspect that body mechanics play a very important part in both the production and the treatment of chronic rheumatism.

**Local Active Exercises.**—Although arthritis is mainly an involvement of the articulations, the interrelation between the joints and the muscles responsible for the joint action is such that one cannot be disturbed without affecting the other. While our therapeutic efforts are focused on the joints themselves, we cannot afford to neglect the muscles. An inactive joint will produce inactive muscles which will lead to disuse atrophy. This atrophy affects the muscles in various degrees and in a general way we may say that the extensors and abductors will atrophy sooner than the corresponding flexors and adductors. This will lead to unbalance of muscles and result in contraction deformities.

As an example we may consider the knee joint. The leverage, muscle power and phylogenesis are all in favor of the flexors. It is a common experience that the quadriceps atrophies readily, and it is therefore important to start the patient early on quadriceps exercises. This contraction-relaxation of the quadriceps can be performed without moving the knee joint, and should be done at least two minutes every hour. This simple exercise will maintain the tone of the quadriceps, prevent atrophy and counteract flexion contraction. The same is true of the extensors of the ankle and toes, the extensors and abductors of the hip, and corresponding muscle groups in the upper extremities.

The characteristic deformities of the hand and fingers in chronic rheumatoid arthritis have always been accepted with resignation by patients as well as by the medical profession. The typical deformity in rheumatoid arthritis is due to disuse, which produces an unbalancing of the muscular pull. This results in flexion deformity in the metacarpophalangeal joints and terminal interphalangeal joints, and extension deformity

in the first interphalangeal joints. To prevent this we must supply adequate circulation by means of paraffin dips and some form of activity for the fingers. These exercises should take the form of gentle continuous movements such as you get in knitting, piano playing, and typewriting. I still have to see the typical finger deformity in an arthritic patient who has had to keep her fingers active during the major part of the day.

**Passive Manipulations.**—Passive stretchings of arthritic joints are used much less today than in former years. However, they have been used for so many years that they must have something to recommend them. It is probably a question of selecting the proper cases. We all recognize that a joint with arthritic pathology often shows periarticular fibrositis and muscular spasm. The ideal condition for manipulations is slight change in the joint and marked periarticular involvement. This is found in both rheumatoid arthritis and osteo-arthritis in subacute and chronic stages.

Two principles underlie these passive manipulations. The first one is that the joint surfaces should be separated, or maximum traction should be exerted on the joint. The second one is that the motions undertaken should be based on the normal kinesiology of the joint in question. The first point is illustrated in the manipulation of a shoulder. The patient is in a sitting position, and the manipulator places his knee in the axilla, thereby exerting traction in the shoulder joint. From this position the shoulder is carried through flexion, extension, abduction, adduction, external and internal rotation.

The second point is shown in the manipulation of the ankle and foot. The patient lies on his back with the leg under treatment abducted in such a way that the manipulator, standing inside the flexed knee, can exert countertraction against the thigh with his body, and actual traction on the foot with both hands. One hand grasps the heel, the other hand grasps the forefoot. While maintaining traction we go through normal motion in the tibio-astragalar joint, the astragalocalcaneal joint, the midtarsal joint, the tarsometatarsal joints, the intrametatarsal joints, the metatarsophalangeal and interphalangeal joints.

This type of manipulation under traction is easier on the joint than the old method of forced stretching on pressure

against the joint. If a hip joint is to be manipulated, have patient on back, grasp the extended leg by the ankle, lean backward and use your weight for traction, while you go through the hip motions. This applies to all joints of the body. Such manipulations may produce temporary pain, but should not cause a sleepless night, or discomfort the next day. Often the patient experiences a sensation of better control of the joint and less apprehension of defeat in the function of a joint.

We may summarize our ideas on massage and exercises in arthritis by saying that these two valuable agents are of great importance in the management of the arthritic patient. We may go further and say that they are indispensable in arthritic therapeutics. They are not specific remedies, but are complementary agents to every treatment that is being used in arthritis. Instead of leaving the prescription of massage and exercises to the gambling instinct of the technician, it would undoubtedly benefit the patient if the doctors were familiar with the physiologic action of these agents, and were able to prescribe them for his patient for a definite purpose.

### ELECTROTHERAPY IN CHRONIC ARTHRITIS

It is the present consensus of opinion that chronic arthritis is a "constitutional" disease with local changes in the joints as well as disturbances in the circulation of the skin and in general metabolism. In some cases a primary focus of infection may be responsible for supplying the stimulus for the systemic and local changes. Physical agents offer a wide range of potent measures for influencing the general condition—the focus of infection, the changes in the joints and also for relieving local and general pain and safeguarding and restoring function.

The principal physical measures in the treatment of chronic arthritis are heat, massage and exercise; in addition, certain counterirritation measures. The various forms of these measures are considered in different sections of this symposium and this presentation is to be confined to the consideration of electrical and radiant energy. In actual practice one cannot separate these measures from the other forms of physical treatment. The simpler electrical measures are important from the standpoint of the general practitioner because they lend themselves to well-controlled use in the office and they are also valuable for properly supervised home treatment.

#### ELECTRICAL AND RADIANT ENERGY IN THE TREATMENT OF CHRONIC ARTHRITIS

- (A) General or systemic measures:
- Large radiant heating units.
  - Electric light cabinets.
  - General diathermy or short-wave diathermy.
  - Heliotherapy.
  - Galvanic baths.

## (B) Local measures:

- Luminous heat and infra-red radiation.
- Diathermy and short-wave diathermy.
- High frequency sparking (Oudin current).
- The galvanic current.
- Ionization with vasodilating drugs.
- The static wave current.
- Low tension wave currents.

**Electrical Heat.**—Thermal measures are potent agents in influencing circulation and metabolism. In rheumatic arthritis the heat-regulating apparatus is disturbed and the circulation is out of order, as manifested by its variations in the skin and extremities, especially the fingers and toes. Other parts of the body, especially the organs of the abdomen, which are not accessible to observation undoubtedly are the seat of the same variations. The vasomotor control is unstable. The basal metabolic rate is changed and the blood pressure is low. Systemic heating therapy in all forms of chronic arthritis results in the acceleration of the pulse rate, a general vasodilation in the skin; the circulating blood volume is increased, while the alveolar carbon dioxide tension and the alkalinity of the blood show a decrease. Metabolism always shows a considerable increase on any rise of body temperature; according to the temperature law of Van't Hoff, for every rise of  $10^{\circ}$  C. the rate of oxidation is increased two and one-half times.

The clinical object of systemic heating therapy is stimulation of the general circulation and the increase of body metabolism; the local changes are only indirectly affected, yet in many instances following general thermal treatment there is a decrease of pain and swelling and functional improvement in the affected parts. Rheumatic exudations have been likened to smoldering foci of disease, and heat—properly used—often effects their resorption.

For mild general heating in physicians' offices *large incandescent lamps* or *infra-red generators* of 1000 to 1500 watts capacity may be applied for one-half hour or longer. Mild body heating may also be obtained from high frequency sources in the form of general diathermy, short-wave diathermy and in occasional instances autocondensation. *Electric light cabinets* are employed in the institutional treatment of arthritis; the

duration of each treatment is from eight to fifteen minutes, according to the tolerance of the patient; it is usually followed by a tepid shower and a half-hour rest.

*Artificial fever treatment* has found a fairly extensive clinical use during the past few years. General diathermy, short-wave diathermy in a condenser and electromagnetic field and heating boxes have been utilized to produce hyperpyrexia. The consensus of opinion is that such treatments, although frequently very exhausting to arthritic patients, produce no other than temporary improvement in the general condition and the local symptoms. For this reason there seems to be little advantage of fever therapy in rheumatoid arthritis over the time-honored systematic use of mild general thermal measures. In acute and chronic arthritis due to gonorrheal infection, on the other hand, fever treatment has proved almost specific and is being now employed generally, if local treatment fails to clear up the affected joint.

The selection of a systematic thermal measure must be made on the basis of seasoned clinical experience and within the limits of the expected individual tolerance. No general heating measures should ever be instituted in a haphazard way and without definite indications. Provision must be made for patients to cool off and rest after any general heat treatment. A well-planned course of general thermal measures should be followed by a period of no treatment or be alternated with suitable local treatment.

*Local heat* treatment has as its object the increase of local blood and lymph circulation and local tissue metabolism, promotion of resorption and restoration of function. An even more important effect of suitable local heat application is that of the relief of pain, the symptom which is the most bothersome and most depressing, next to the stiffness and limitation of motion.

For simple yet efficient heat application in the home and in the office, *infra-red* and *luminous heat generators* mounted on suitable stands are now universally preferred, and have largely replaced the former cumbersome dry baking apparatus and light boxes. The penetrating effect of the luminous heat is somewhat deeper than that of *infra-red* radiation. For home treatments patients should be instructed to use these appliances

for one-half hour two or three times a day over the affected joints. Such heating should be followed by gentle stroking massage applied by a well-instructed member of the household. Well-planned home treatments help to keep patients comfortable and allow the bridging of the time between office visits.

*Diathermy* has become recognized in recent years as an efficient form of deep heating. Clinical experience has shown that especially in cases of osteo-arthritis localized in one or two of the larger joints or in the spine, diathermy will do more for local relief of pain, promotion of resorption and restoration of function than any other physical measure; it also lends itself easily to a combination with other measures. In the so frequent bilateral knee involvement of the osteo-arthritic type in middle-aged women diathermy combined with suitable rest will give complete relief in the great majority of cases. In traumatic arthritis, diathermy followed by massage or the static wave current is likewise the line of first attack. In gonorrheal arthritis diathermy may serve for the eradication of the focus of infection in the genital tract as well as for the treatment of joint changes.

The newer method of *short-wave diathermy* has been shown to exert more penetrating heating effect and its technic is more simple; on the other hand its dosage regulation compared to diathermy is crude and there is a possibility of overheating deeper avascular structures. The clinical results with its application are the same as with diathermy.

*High frequency sparking* (known as the Oudin current) has a well-defined use for mild counterirritation in fairly sub-acute arthritis involving several joints, also in diffuse pain of neuritic character. It should be employed following external heat treatment. In painful involvement of small finger joints the hot-air douche, produced by an ordinary hot-air drier, affords usually a marked analgesic effect.

**Heliotherapy.**—The beneficial effect of both natural and artificial light treatment in cases of tuberculous arthritis are well known, and is explained almost entirely through the constitutional effects of the irradiation and of the other factors—elevation, mountain air, rest and relaxation. These factors also explain the good results in certain forms of chronic arthritis following sojourns in heliotherapy resorts. The rationale

of light therapy may be based on three considerations: first, the tonic effects of radiation, especially in patients with asthenic constitution and rheumatoid arthritis; second, the findings of many investigators that chemical, thermal and other "insults" of the skin provoke or increase the defensive power of the body partly by a direct effect on improving immunity and partly by stimulating the immunizing mechanism through the absorption of the products of tissue damage, for ultra-violet irradiation, causing a varying degree of dermatitis, acts like foreign protein therapy; third, the direct thermal effect of the infra-red rays.

**Galvanic Current and Ionization.**—The time-honored *galvanic current* offers a useful adjunct in treatment of chronic arthritis especially the atrophic type. It brings about prolonged hyperemia of the skin and has some effect on the deeper circulation by reflex or direct penetration. Good results have been reported in the local treatment of joints where fibrous tissue changes have taken place. For therapeutic efficiency it is important that as large amount of current as can be borne be applied for a sufficiently long time, at least one-half hour sessions.

*Ionization with vasodilating drugs* has been extensively employed in recent years. The rationale of this treatment is based on research work pointing to the close connection between disturbed peripheral circulation and arthritic conditions. These studies showed that in arthritis there is a tendency in the capillaries of the skin toward relatively empty vessels and a sluggish flow of blood. There is much less blood as a whole in fewer capillaries to be seen in many cases of arthritis than in normal persons. The circulation is often sluggish and interrupted and there is apt to be present a contrast between the venous and the arterial side.

Histamine and choline compounds are introduced through the polarity effect of the galvanic current—from the positive pole. They penetrate the deeper layers of the skin and exert local as well as systemic effects; acting as antagonists to atropine, they stimulate the parasympathetic nerves and dilate the peripheral vascular system. *Mecholyl* ionization has been found a useful palliative treatment in rheumatoid arthritis where other methods of physical therapy directed to the relief of the local condition failed. This method is especially ap-

plicable in affections of the joints of the hands and fingers. *Histamine* ionization brings about a more vigorous local reaction and seems to be preferable in rheumatic myositis and neuritis.

**Electrical Massage and Exercise.**—The *static wave current*—when static apparatus is available—offers the best effect of a gentle, pleasant molecular massage and “decongestion.” Whenever there is edema and marked stasis it can be reduced by the static wave current with less effort and trauma than hand massage. Static sparks applied around tense and spastic joints aid their mobilizing; patients usually feel markedly limbered up after a series of well-placed sparks.

In visceroptosis and sluggish bowel activity of arthritic patients, exercise of the abdominal muscles by voluntary work or by a *low-tension wave current* (the surging faradic or interrupted sinusoidal) may be indicated. Its systematic application aims to improve the tone of the musculature, peristalsis, the venous return from the abdomen to the heart and also glandular function. Electrical exercise of the large muscles of the extremities may aid in maintaining the tone and in preventing atrophy so frequent in the later stages of arthritis. It has been shown that muscular contractions of this kind partake more of the nature of massage than of active exercises and have the advantage of making fewer demands upon the cooperation or energy of the patient than exercise does.

**Scheme of Treatment.**—The large number of electrical measures described constitute an invaluable aid in the constitutional therapy of chronic arthritis and are the mainstay of its local treatment. It is evident that all these measures must be employed in conjunction with a plan of general medical treatment. It must be emphasized again that in the routine management of arthritis one cannot separate electrical measures from other physical measures such as massage, exercise and the various forms of hydrotherapy. All these measures may be used in suitable combination or alternation. A change of methods from time to time is desirable because any form of stimulus employed over a long period of time will lose some of its effect. In the following brief description of the scheme of treatment in the principal types of chronic arthritis, therefore, all available physical measures have been taken into consideration.

1. *Osteo-arthritis*.—The average patient with osteo-arthritis is usually a well-nourished individual after middle age; in its etiology trauma, overuse or metabolic factors are the most frequent causative factors and not infection; the joint changes affect fewer and larger joints. Early cases of this type can be given almost complete relief by suitable physical measures in conjunction with suitable dietetic régime and regulation of habits. Diathermy to the joints combined with massage or the static wave current is usually quite effective. In advanced cases or cases affecting several joints a course of careful general heating may be indicated; this may be done in the form of a stay at a hot spa. In cases complicated by synovitis the static wave current is valuable.

2. *Rheumatoid Arthritis*.—This form of the disease occurs in younger persons usually in poor stage of nutrition. Infection may play a rôle in its onset and it affects, as a rule, many of the smaller joints. In this condition the entire range of available physical measures must be drawn upon to aid the general medical treatment. Mild general thermal treatment is indicated from the beginning to aid general circulation. Early heliotherapy, natural or artificial, is important for general tonic effects. Suitable exercises, general as well as local are to be instituted to correct posture and prevent deformities. For local treatment, especially at home, daily use of luminous or infra-red sources followed by gentle massage and active exercise is advisable. Ionization with vasodilating drugs is valuable in reducing swelling and pain in small joints which do not respond to mild thermal treatment.

3. *Gonorrheal Arthritis*.—A typical affection of one single joint is usual in this infectious form of arthritis; an attack on several joints occurs not too infrequently. The sovereign treatment consists of intense heating to the suspected focus of infection, the affected joints or to the entire body. In the painful acute stage joints usually can stand only mild continuous heating from radiant sources; diathermy at this stage is apt to bring about a severe local reaction. In the chronic stage, intense diathermy or short-wave diathermy locally applied to the joints will clear up many cases; in resistant cases and those affecting several joints, artificial fever therapy is indicated and is effective in a very large percentage of cases.

### PHYSIOTHERAPY IN ARTHRITIS: HYDROTHERAPY

HYDROTHERAPY is a comforting and widely accessible form of conductive heat that has been used for the pains in arthritis since years before anything was known about the disease. Cures or spas, where hydrotherapy was the main form of treatment, have been relief-giving and utilized all over Europe since the time of the Romans. Mysterious powers have been claimed for different waters and it is barely possible that some of them, due to what is now known to be radio-activity, produce more effect than bland waters containing varying amounts of salts. The spas frequented by rheumatic patients depend largely upon their salt content for their accredited, varied effects. We know that these baths at European spas, combined with the regular régime, are beneficial for many cases of arthritis but it is a question what percentage of this benefit is derived from the water itself.

In the United States our few well-known cures, such as Hot Springs in Virginia, Hot Springs in Arkansas and Saratoga Springs, are too near the telephone for patients to relax completely. When they really wish to take treatment, they prefer to go abroad, both for the trip and the seriousness of the atmosphere which makes them live up to the prescribed régime. It is to be regretted that the American cures are more places for social gatherings than serious medical treatment.

Some of the cures combine their water baths, which may be included in the term "hydrotherapy," with baths of either radio-active or ordinary mud. These mud baths are generally taken in tubs and are followed by sprays of water to clean it off. Mud from the northern part of Italy is obtained from the

bottom of crater lakes and hence has a high content of volcanic ash, and because of its adhesiveness, can be used for mud packs. More radio-activity is accredited to this kind of mud than to others. Be that as it may, it is a moot question how much benefit is derived from any radio-activity either in mud or water. But this quality has a great sales attraction for the different spas.

The hydrotherapy technic used at these cures is immersion for various lengths of time, with or without manipulation. In England it is usual to give exercises to a patient while immersed in the water and under-water douches are administered with the stream directed at the affected joint. Exercises under water undoubtedly are more beneficial than those on land because the limb floats and less muscular effort is needed. This has been brought out since attention has been directed to hydrogymnastics for the treatment of the paralytic. A great deal of work is being done on paralytics and it is hoped that eventually it will come about in this country that arthritics receive the benefit of hydrogymnastics. This kind of exercise in warm water helps to relieve the pain due to muscle spasticity.

For the treatment of arthritis of the joints of the feet, ankle, hand and wrist, the whirlpool bath is particularly sedative. The original whirlpool bath was designed during the World War. In this, water was forced through a nozzle under pressure into a cylindrical tank and air was sucked in with it, making a strong stream of bubbles and giving a very delicate massage. Agitated water can be tolerated by the patient at a higher temperature than if it were still. The whirlpool bath also has been found to cause a more prolonged hyperemia of an extremity than any other method, including electrical treatments.

The whirlpool bath, hydrogymnastics and the under-water douche without air are applicable for direct effect on specific joints. They are combined, as is being done by Currence in New York. He uses a tank for hydrogymnastics and with the Titus whirlpool agitator directs a stream of water toward the affected joint while exercises are given.

Arthritis is a constitutional as well as local condition and constitutional effects are easily obtained by all forms of hydrotherapy. Not only the general immersion baths are employed but patients frequently are put in foam or bubble baths. A

foam bath, as the name implies, is a tub full of foam. This is generated by mixing a few drachms of a saponin solution with about 3 inches of water in the bottom of a tub. A long frame with perforated tubes in it is immersed in this water and air or oxygen are forced through this mixture to form the foam. With this apparatus a tub can be filled with foam in from ten to fifteen minutes. The patient then gets into the tub and is completely covered by the foam, which restricts the radiation of the heat from the entire body. The foam itself is also hot and great perspiration is induced with the natural elimination of toxins. These baths have a very sedative effect upon patients, especially if they are of the nervous type.

With the same rack placed in an ordinary bath tub filled with water, air can be forced up through the water, giving a general massage with small bubbles to a patient's entire body. These bubbles may be of ordinary air from a pump, carbon dioxide or oxygen from tanks.

Hydrotherapy as an adjunct to the treatment of arthritis has the great disadvantage that it cannot be given conveniently in a doctor's office or in a patient's home. It requires hospital equipment and a real department in which everything is available, as well as hydrotherapy.

Hydrogymnastics should be preceded by applications of convulsive heat, either radiant or electrical, and tonic baths are best accompanied by ultraviolet light baths. Massage in or out of water should also be given. The use of a single modality in physical therapy is not rational treatment and hydrotherapy, through stimulation of the circulation, is more symptomatic than anything else.

#### THE GENESIS AND TREATMENT OF EDEMA IN BRIGHT'S DISEASE

PHYSICIANS in the eighteenth century knew that dropsy resulted from a number of causes. Apparently Blackall and Bright were the first to recognize its association with morbid changes in the kidneys. Bright's associate Dr. Bostock was, indeed, aware of the fact that the specific gravity of the serum was sharply reduced in certain patients in whom dropsy was observed.<sup>1</sup> He associated the low specific gravity correctly with loss of plasma albumin in the urine; but he did not realize that the dropsy was often causally related to the deficit of plasma proteins. It remained for Starling<sup>2</sup> to propose that the osmotic attraction for water by the plasma proteins was a force of great importance in the maintenance of exchange of fluid between the blood stream and the interstitial fluids. Starling believed that the exchange of fluid between the capillary blood and the tissues was controlled by at least two opposing forces, namely, the hydrostatic pressure within the capillaries which tended to force fluid out of them and the osmotic attraction of the plasma proteins, which tended to draw fluid into the blood stream. That these factors are important in the edema in nephrosis and nephritis was pointed out by Epstein<sup>3</sup> and Govaerts.<sup>4</sup> Thus it is that hypoproteinemia has come to be recognized as one of the chief causes of edema occurring in chronic nephritis and nephrosis. Other types of edema also occur, especially in the acute onset and during the terminal stage of nephritis. The typical "nephritic" or "nephrotic" edema, however, is associated regularly with, and in large part due to, plasma protein deficit.

## THE NON-NEPHROTIC EDEMA OF THE ONSET OF ACUTE NEPHRITIS

This edema occurs *before* plasma protein deficit develops. It exhibits characteristic predilection for the face and especially the eyelids. The ankles, feet, hands, scrotum and labia are usually involved less frequently and in the order named. It appears that this type of edema is due to increase in permeability of the capillary wall which allows the escape of protein into subcutaneous tissues. This extravascular protein exerts enough osmotic attraction to draw water from the blood plasma in sufficient quantities to be recognized as excess fluid in the tissues. Edema fluid from such patients, unlike that from patients with nephrotic edema, is rich in protein. The escape of proteins from the circulating plasma is evidence that the permeability of the capillaries is increased.

The cause of the increase in capillary permeability is unknown. Most observers have suggested that it is toxic in origin chiefly for two reasons. It occurs usually closely associated with infection or an episode involving anaphylaxis. Its appearance resembles edema produced by injection of toxic substances.

The non-nephrotic edema of acute nephritis is transient, seldom lasting more than a few days or weeks. It causes the patient little discomfort and requires no treatment. However, it is important to recognize it chiefly for two reasons. It calls attention to a serious disease and it suggests that blood vessels other than those of the kidneys are involved in the morbid process.

Often this edema is so transient or mild that it is not noticed by the patient. It may be present in the morning when the patient awakes and disappear as the day progresses. It is often dismissed by him as due to gastro-intestinal upset, fatigue or alcohol. The initial stage of Bright's disease is often therefore overlooked and attention is called to the disease only after it has entered the chronic stage. Thus the non-nephrotic edema of acute nephritis may be viewed as an important danger signal, which in itself needs no treatment, but which urgently demands that the underlying disease of the kidneys and blood vessels receive attention.

## NEPHROTIC EDEMA

Edema due chiefly to abnormally low plasma proteins, so-called "nephrotic edema," occurs during the course of both chronic hematuric nephritis and during nephrosis. Often the differential diagnosis between them is difficult or impossible. Hypoproteinemic edema in the majority of adult patients, however, is associated with hemorrhagic nephritis.

Nephrotic edema is usually obvious and obstinate. In the so-called "preedematous stage" the skin feel doughy and lacks normal elasticity. When frank edema appears, it affects those parts of the body most subjected to the force of gravity. If the patient is up it will be most conspicuous in the ankles and legs, while if bedridden, the sacrum, scrotum, labia, back, face and arms are also involved. In some cases ascites is prominent.

As the terminal phase of the disease approaches, the nephrotic edema may continue, but often the plasma proteins rise spontaneously and the edema disappears. This terminal "dry phase" is sometimes followed by edema due to cardiac failure.

**Causes of Nephrotic Edema.**—A number of different factors are responsible for the occurrence of nephrotic edema, the better understood and possibly more important among these being: (1) hypoproteinemia with consequent loss of osmotic attraction of the plasma for water, (2) the hydropigenous effects of salt in the tissues. Most evidence<sup>5</sup> does not support the belief that the ionic excretory power of the kidneys in nephrotic patients is qualitatively different from kidneys of normal persons, although the tissues of edematous patients on a salt-poor diet appear to retain more salt and consequently water than do normal persons on the same régime. Studies on the drainage of fluid by way of the lymphatics away from the edematous areas show that it is very active.<sup>6</sup> This is in marked contrast to the stagnant lymphatic drainage in cardiac edema.

Deficit of plasma protein, as has been said, is one of the most important causes of nephrotic edema.<sup>7</sup> In normal human beings the total plasma protein content is about 7 Gm., the albumin 4.5 and the globulin 2.5, per 100 cc. of plasma, and the specific gravity is 1.027. But if the total plasma proteins in an adult fall below 5 Gm., the albumin below 2 Gm., and the specific gravity below 1.023, edema usually appears. When

the total protein is between 4 and 5.5 Gm. and the albumin between 2 and 3 Gm., edema may or may not be present, often depending on whether salt restriction and rest in bed are prescribed. In children and occasionally in adults somewhat less plasma protein may be required to prevent the appearance of edema.

When hypoproteinemia occurs in Bright's disease it is chiefly the albumin fraction in the plasma that is lowered. Since the osmotic activity of the albumin is about three times as great, per gram, as the activity of globulin, the effect on the edema-preventing colloid osmotic activity is greater than if the globulin were lost.

Important as hypoproteinemia is in the genesis of nephrotic edema, other, as yet unknown factors, also influence the fluid retention. Edema may disappear without any rise in the depressed plasma protein level.<sup>8</sup> This is often observed following fever and seems to occur in children more commonly than in adults. Furthermore, several patients have been described in medical literature in whom hypoproteinemia has occurred without the simultaneous appearance of edema. Edema has been observed to disappear in patients receiving high protein, low salt diets, even when the plasma colloid osmotic pressure is below the level at which edema is usually present. But the tendency to edema still appears to remain in most cases until the plasma protein concentrations increase above their critical levels.

**Causes of Hypoproteinemia.**—Since the edema fluid contains only very small amounts of protein, there is little reason to believe that the permeability of the capillary walls is more than slightly increased in the edema of *chronic* nephritis.

The causes of the lowered plasma proteins must be searched for elsewhere. The most obvious of these is loss of protein in the urine. Many patients lose as much as 25 Gm. of protein a day. It has been observed that when protein excretion exceeds 6 Gm. a day nephrotic edema usually occurs, although this correlation is only approximate. Protein loss in the urine places a heavy demand on the synthetic power of the body and constitutes probably the most important cause of hypoproteinemia in Bright's disease.

A second important cause of plasma protein deficit is a diet

low in protein content. This was illustrated during the war by the appearance of edema among the population of countries where protein foods were sharply curtailed. Such nutritional edema has also been produced in dogs fed low protein diets.

The protein lost in the urine must obviously be replaced either from the tissues or from the constituents of the diet. It is common clinical experience that Bright's disease is a wasting disease.<sup>9</sup> Especially when edema disappears is it evident that the body tissues have been drawn upon and seriously depleted. Malnutrition as well as Bright's disease produces hypoproteinemia especially in the albumin fraction; hence malnutrition alone must be reckoned as an important factor in the genesis of hypoproteinemia.<sup>10</sup>

It is possible that a third cause of hypoproteinemia is inability of the body to synthesize sufficient protein to balance the loss in the urine. Protein intake may be adequate yet the loss of protein so great that the body appears to be unable to replace it fast enough. Sometimes, however, a patient is seen whose proteinuria disappears, and who receives an adequate protein diet, and yet whose plasma proteins do not rise to a normal level. Whether this is due to impaired ability to synthesize plasma protein or to change in the mechanism which controls the level of proteins in the plasma is not known. It appears unlikely that impaired ability to synthesize plasma proteins is common in Bright's disease since disappearance of proteinuria is usually accompanied by a rise in them. Furthermore during the terminal stage of the disease, when this power could be expected to be most seriously impaired, the plasma proteins often rise and edema disappears unless complicated by coexistent edema of cardiac origin.

#### SALT AS A FACTOR IN THE PRODUCTION OF NEPHROTIC EDEMA

It has been known for years that the intake of salt influences the appearance and extent of nephrotic edema. Water cannot be retained without an equivalent amount of salt, nor salt without an equivalent amount of water.<sup>11, 12</sup> Even in normal persons amounts of salt of the order of 35 to 40 Gm. in a day will produce edema. But in subjects with edema and decreased colloid osmotic pressure of the blood there is a magnified tendency to retain salt along with sufficient water to form

physiologic saline solution. Salt retention does not of itself usually produce edema, but associated with hypoproteinemia it greatly increases it. The sodium and not the chloride ion appears responsible for the hydropigenous effect of salt. Potassium salts, on the contrary, have no hydropigenous action.

#### DETERMINATION OF PLASMA PROTEIN

Proper understanding of the cause and treatment of edema occurring during Bright's disease is so dependent on knowledge of the amount of proteins in the plasma that it appears useful to present a simple bedside method for their indirect estimation.<sup>13</sup> The method now described ascertains merely whether the specific gravity of the plasma is above or below the critical edema level, 1.0235. The blood is mixed with 1 mg. of heparin per cubic centimeter, or with not more than 2 or 3 mg. of oxalate, and is centrifuged. A drop of the plasma is let fall about 2 cm. from a pipe into a tube of organic fluid having the density 1.0235. For such fluid one may use pure phenyl fluoride,  $C_6H_5F$ , or a mixture of 1 volume of xylene with 2.06 volumes of phenyl chloride,  $C_6H_5Cl$ . If the plasma is sufficiently rich in protein to prevent hypoproteinemic edema, the drop of plasma will sink to the bottom. In contrast, the drop of plasma from a nephrotic subject will rise to the surface of the organic fluid. From the rapidity with which the drop falls or rises one can estimate roughly whether the specific gravity is near the critical level 1.0235 (very slow rise or fall), is near the normal 1.027 (rapid fall), or near the low extreme of nephrotic hypoproteinuria (1.019) (rapid rise to surface).

#### TREATMENT OF NEPHROTIC EDEMA

Since body tissues are wasted by the continuous loss of protein in the urine, one of the first objects of treatment of nephrotic edema is to replace this loss. This can be done only by generous feeding of protein.

In the past, protein feeding in nephritis has been guided by theoretical conceptions which in the light of more complete data appear to be incorrect. Impressed by the fact that end-products of protein metabolism, especially urea, were not adequately cleared from the blood by damaged kidneys, physicians

reduced protein in the diet hoping thereby to reduce the work of the kidneys. It was believed, further, that urea or other products of protein metabolism might in themselves be toxic when increased in amount in the blood.

Recent evidence from a number of clinics,<sup>11, 14, 15, 16</sup> however, has shown that fairly generous amounts of protein in the diet do not appear to intensify the morbid process in the kidneys as measured by the usual tests of renal efficiency. On the other hand, data are insufficient to decide whether diets containing 80 to 100 Gm. of protein hasten or retard progress of the disease toward its fatal termination.

It is now clearly established that definite benefits to tissue nutrition, normal water balance, and general strength, may result from avoiding low protein diets and allowing from 80 to 100 Gm. of protein in a normal, well-balanced diet with adequate amounts of vitamins. Shift from low to higher protein diets causes protein storage in the tissues of the patient. This diet aids in combating the wasting and malnutrition, a prominent sign of the disease, and helps to increase plasma proteins and consequently to decrease edema. This happy result may change the entire outlook for the patient. In place of being bedridden from edema and malnutrition the patient often resumes nearly normal activities. It is especially desirable that children receive adequate amounts of protein in their diet to avoid interference with normal growth.

Marked variability is shown by patients in their response to protein feeding. Those that have consumed ordinary amounts of protein may not show benefit from its increase in the diet until two months or more. The diet should not, therefore, be abandoned after a few weeks' trial. By no means do all patients respond by rise in plasma proteins when protein is increased in the diet. If the individual is already well nourished and if excretion of protein in the urine does not exceed 6 Gm., the protein in the diet may be varied within relatively wide limits without significantly affecting the level of plasma proteins.

In this clinic a diet containing from 80 to 100 Gm. of protein has been observed to be adequate for an adult losing less than 10 Gm. of protein a day in the urine. Usually there is little to be gained by using higher protein intake and much to

lose as digestive disturbances may readily occur. Children, however, consume diets containing about 3 Gm. of protein per kilogram of body weight with apparent benefit.<sup>17</sup> The ratio of animal proteins (meat, eggs, milk, casein) to vegetable protein given in the diet in this clinic is about 2 to 1. Casein\* taken with milk is a cheap and convenient form in which to administer it but skimmed milk powder is better tolerated by children.

### SALT RESTRICTION DESIRABLE

Salt restriction is imperative in the treatment of nephrotic edema. The ordinary diet contains 10 Gm. or more of salt but restriction to about one fourth of this amount is compatible with perfect health. In adult patients with nephrotic edema it is desirable that not more than 2 to 3 Gm. of salt be allowed. It should be remembered, however, that as the disease approaches the terminal stage, *inability* to retain sodium chloride develops, several grams of salt per day may be excreted even on a salt-free diet, and hypochloremia may occur. This appears in some patients to hasten the onset of uremia. The need for salt restriction often disappears along with the plasma protein deficit during this stage. In children the restriction of salt is of paramount importance. Less than 1 Gm. a day in the diet should be allowed. There is no retardation of growth and development with such restriction.<sup>17</sup>

### PREPARATION OF CASEIN

The following recipes have been prepared by Miss G. Drew.

*Casein Preparation No. 1.*—Milk or water 150 to 200 cc., casein 15 to 35 Gm.; mix together slowly, stirring until smooth.

*Casein Preparation No. 2.*—Cocoa 2 Gm., sugar 5 to 10 Gm., water 25 cc., milk 175 cc., casein 15 to 35 Gm. Scald milk and mix cocoa, sugar and water, cook for five minutes and add to scalded milk. Cool and mix with casein slowly, stirring until smooth.

*Casein Preparation No. 3.*—Milk 165 cc., egg 35 Gm., sugar 5 to 10 Gm., vanilla to flavor, casein 15 to 35 Gm. Make

\* An edible casein powder prepared by the Casein Manufacturing Company, 350 Madison Avenue, New York, may be useful in enriching the protein content of diets for adults. It is cheaper than meat protein.

eggnog with milk, egg, sugar and vanilla. Mix with casein slowly and stir until smooth.

Liquid ingredients may be either warm or cold, but never hot when mixing with casein.

Salt-poor diets may be best prepared merely by avoiding foods to which salt has been added. No naturally occurring foods contain important amounts of salt, except those in which sea water is mixed (*e. g.*, clam and oyster juice). Salt substitutes are ordinarily not necessary and often impart an unappetizing taste to the food. The palatability of food may be increased by use of flavoring with onion, lemon juice, vinegar, mustard, pepper, nutmeg, etc.

#### WATER RESTRICTION UNDESIRABLE

Water restriction is unnecessary. Patients with nephrotic edema will not retain water unless with it they retain a physiologically equivalent amount of sodium salts. Even large volumes of water given without salt are excreted by these patients without difficulty; in fact, the diuresis may hasten salt excretion and reduction of edema. Limitation of water produces unnecessary and useless suffering from thirst, and reduces urine output to volumes below that at which renal excretion of solids is most efficient (*e. g.*, with a urine volume of 0.5 cc. per minute urea is excreted only half as rapidly as with a volume of 2 cc. per minute). Only when cardiac failure occurs, and it is rare in nephrosis or the nephrotic stage of Bright's disease, is water restriction justified.

#### SURGICAL TREATMENT

If edema fails to disappear after a diet adequate in proteins and vitamins and low in salt has been given for four months or more and bed rest enforced, denervation of the kidneys may be considered. As this operation has only been employed for this purpose recently we do not yet know the physiologic changes by which it diminishes the tendency to edema.<sup>18</sup> Denervation of one kidney may be as successful as denervation of both. The operation need have no mortality. It may be performed under local anesthesia though this appears to be rarely necessary. If the urea clearance is below 20 per cent

Fig. 137.—Example of a patient suffering from Bright's disease who had consumed an inadequate diet. Edema was intense, but within two months had subsided when a diet containing 75 Gm of protein and 2.5 Gm of salt was given. Associated with the loss of edema was a rise in plasma proteins but no significant change in the output of protein in the urine.

FIG. 135.—Example of a patient in the nephrotic stage of chronic Bright's disease. Edema and ascites had been his most persistent and disabling sign. He was free of them only for short periods. Following renal denervation he was free for two and one-half years in spite of consumption of 1000 mg. of salts. No adequate explanation has been found for this.

of normal there is no justification for performing it because, except insofar as it betters the clinical condition of the patient, it does not affect the renal efficiency as judged by urea clearance or ability to concentrate urine.

For several months after operation protein in the urine may be sharply diminished and a moderate rise in plasma protein may occur. In some patients this persists but in others return to the preoperative rate of excretion of protein occurs. Denervation does not lead to persistent polyuria in our experience. Apparently almost independent of the plasma protein level the edema may completely disappear and salt may be added to the diet without reappearance of edema. As a result of disappearance of the edema the clinical condition of the patient is greatly improved. A favorable result does not always occur, but there have been no observations made on these patients which indicate that harm has been done.

#### MEDICINAL TREATMENT

**Diuretics.**—Opinion differs as to the desirability of employing diuretics in the treatment of nephrotic edema. It is generally agreed that they are not as useful as in the treatment of cardiac edema.<sup>19, 20</sup> After trying the various organic and mercurial diuretics, and the acid-forming salts, such as ammonium chloride and nitrate, we have in the Rockefeller Hospital practically abandoned all of them in treatment of nephrotic edema, except urea. Large doses, 30 to 60 Gm. per day, are required, and can be continued for prolonged periods. They may assist in keeping edema within tolerable limits, and in obviating the necessity of abdominal tapping. The effect of the urea lasts only as long as the administration is continued. The hydropigenous factor of the disease does not disappear until the plasma proteins rise above the critical concentration.

**Blood Transfusion and Acacia.**—Attempts have been made to increase the colloid osmotic pressure of the plasma by blood transfusion or administration of colloid such as gum acacia. Actually the amount of plasma protein added by a single blood transfusion is not great (25 to 35 Gm.) and may be quickly lost in the urine. Intravenous injection of pure gum acacia (30 Gm. in 300 cc. of water) may initiate diuresis

Occasionally during administration of acacia a shocklike syndrome appears. We have also seen a serious reduction of renal efficiency follow acacia injection. The acacia is said to localize eventually in the liver, and may damage that organ. We have entirely abandoned the use of acacia as a diuretic in nephrosis.

### CARDIAC EDEMA

Edema due to cardiac decompensation may occur at any stage of Bright's disease. It is, however, rare during the acute and intermediate chronic stage. During the terminal stage it is a usual occurrence and may be chiefly responsible for the edema or may add to the edema already present due to hypoproteinemia.

Cardiac edema is due chiefly to increased hydrostatic pressure in the capillary bed. Increase in the permeability of the capillary walls due to reduction in blood flow and its attendant tissue anoxemia also plays a part. As a result, some protein is lost into the tissues. The edema fluid contains more protein than edema fluid from a nephrotic but less than that from an acute nephritic.

The signs and symptoms of cardiac failure always accompany cardiac edema. Furthermore the plasma protein content is only slightly lowered in comparison to nephrotic edema in which 5 Gm. or less is present.

**Treatment of Cardiac Edema in Bright's Disease.**—It is of first importance to try to restore the heart to a state of compensation since failure of the heart is responsible for the edema. In patients suffering from Bright's disease, methods for restoring the power of the heart do not differ from those employed in usual practice. Salt restriction is also a necessary part of the treatment. Just as in nephrotic edema the hydropigenous properties of sodium salts exhibit themselves. Since the plasma proteins are not necessarily significantly reduced in cardiac edema it is neither necessary nor desirable to offer the patient more than small amounts of them. Indeed the total intake of food should be somewhat reduced to about 1500 to 1800 calories. When cardiac edema appears the patient is usually so ill that it is inadvisable to force any special diet. The physician may count himself fortunate if the

patient does not lose his appetite entirely and begin vomiting. If pure cardiac edema were present without impending uremia it would be desirable to restrict the fluid intake to about 1000 cc., but it is rare that one sees this. More usual is the combination of cardiac and nephrotic edema in a patient whose renal efficiency is seriously impaired. A middle ground must therefore be chosen. Adequate digitalization must be immediately secured. The diet must be appetizing and not greater in caloric value than 1500 to 1800 calories. It must contain not more than 2 to 5 Gm. of salt provided marked polyuria is not present, in which case 10 Gm. of salt should be allowed. Complete bed rest is essential. Fluid restriction is usually not possible or desirable. While it might, on theoretical grounds, aid in checking more edema formation the good results are not balanced by the bad. Unless a good flow of urine is maintained the clearing of the blood of waste products by the damaged kidneys is not efficient. While diuretics find their greatest field of usefulness in treatment of pure cardiac edema they are of little value when the kidneys are hopelessly damaged. The few remaining glomeruli and tubules are probably already working at maximum capacity and the tubules are unable to reabsorb water. Diuretics can only harm such a kidney. Thus the treatment of edema during the terminal phase of Bright's disease often becomes a compromise between the procedures which are desirable in the treatment of edemas of cardiac and nephrotic origin.

## CLINIC OF DR. I. S. WECHSLER

### THE MONTEFIORE HOSPITAL

---

#### ON THE DIFFERENTIAL DIAGNOSIS OF NEUROSES FROM ORGANIC DISEASES

ONE of the fears which beset every practitioner is that of making erroneous diagnoses of psychoneurosis in the presence of organic diseases. Every physician is occasionally chagrined to find that what he treated as a hysteria or neurasthenia turned out to be a malignancy, a pernicious anemia or leukemia, or a tumor of the brain. While the dangers involved are not nearly so great in the discovery that what passed for gallbladder disease actually was a psychoneurosis, the waste is no less deplorable and the chagrin no less keen. Naturally these errors of diagnosis decrease as knowledge and experience grow, but the perplexities of the conscientious physician usually increase as his knowledge widens.

To allay the fears and prevent the diagnostic errors a number of practical and theoretical criteria are generally laid down, but it may be confessed that they often serve least when the difficulties are greatest. None the less a few general principles may serve to minimize the errors even though they may not eliminate them altogether. It is needless to state that the best defense against mistaken diagnoses is a sound knowledge of medicine and the avoidance of snap judgment even in what appears to be a simple case. Errors of omission are generally at the root of most diagnostic mistakes. This does not mean to say that one should make it a hard and fast rule to "work up" every case with all sorts of tests and examinations when sound clinical judgment counsels against it. Very often insight and understanding, and particularly a careful history, will show the irrelevancy and even the harm of overworking the labora-

tory investigations; but if one is not to err it is generally wiser to do more rather than less through studies.

Perhaps the best general rule, worth repeating though trite by now, is never to make the diagnosis of psychoneurosis by exclusion alone. The fact that no organic signs are present obviously does not mean that there is no organic disease. Naturally their presence speaks for organic conditions, although they do not exclude a neurosis since the two may coexist. But it is well to adhere to the principle that no diagnosis of anxiety or conversion hysteria or neurasthenia or compulsion neurosis should be made unless by means of a thorough history one discovers some psychogenic factors. This may not be easy in unintelligent or uncooperative patients but even in them investigation may repay the effort by uncovering psychic causes if not complex mental mechanisms. In the case of neuroses it is a wise principle to study each case individually and intensively, not to overemphasize isolated signs and symptoms, to study the history, the precipitating factors, the general mental make-up and type of reaction, and evaluate carefully the whole clinical picture.

Another general rule worth adhering to is to make a thorough physical examination even when the diagnosis of hysteria is fairly evident. Not only is this an excellent therapeutic measure, but it may serve to reveal the presence of organic disease when least expected. While a neurotic generally overemphasizes even minor physical complaints, the psychic symptoms may sometimes obscure very important ones. It is also well to reexamine the patient from time to time. Many psychoanalysts feel that it is contrary to good psychotherapeutic practice to make physical examinations in the course of treatment because of the neurotic tendency to seek refuge in somatic complaints and thus avoid the "disgrace" of psychic causes. There is much truth to this, but enough instances abound in which oversight led to rather tragic errors, so that this view need not be taken too seriously. In any case even a neurotic may develop organic disease. A few simple examples will illustrate this.

A young woman of definite hysterical make-up kept bringing an infinite variety of complaints every time she came to the clinic. Among them were

pains in the chest and shortness of breath. All of them were colored by anxiety which was invariably put down as hysterical. Because there was also a history of mild asthmatic attacks and frequent minor colds little attention was paid to the shortness of breath. As a matter of fact it never really amounted to true dyspnea. The need of expediting work in the clinic was another reason for paying scant attention to the lengthy complaints. One day she complained more insistently of her dyspnea and again was sent away with a placebo and the instructions to return the following week. She came back two days later. This time the chest was examined and a large amount of fluid discovered.

A middle-aged man of forty came to the office with a series of complaints which stamped him as a confirmed neurasthenic. He had indulged in self-gratification since adolescence and been impotent all his married life. Mutual frustration over the years and economic difficulties led to marital squabbles which caused and intensified a variety of neurotic symptoms. Among them were headaches and fatigue and lack of interest, which had increased of late. He was treated for years by numerous physicians and finally came to the neurologist. The examination was negative except for bitemporal hemianopsia and beginning pallor of the optic disks. Naturally the suspicion of pituitary tumor arose despite the neurasthenic syndrome. An x-ray of the sella amply confirmed the diagnosis and a successful operation proved it. Incidentally, most of the neurasthenic symptoms cleared up. Whether the pituitary tumor was the cause of the neurosis or developed in the course of it is a fine question worthy of discussion, but the relevant point is that only a careful examination could have served to make the diagnosis. It is understandable how the long history and the absence of so-called "pituitary" symptoms of polyuria, polydipsia, etc., should fail to arouse suspicions and how the diagnosis of neurasthenia should have been maintained for years, but the error of omission still remains culpable.

It is an old clinical observation that psychogenic disorders may simulate almost every organic disease, and it is equally true that many organic conditions can for a long time mask as neuroses. The old adage that one who knows syphilis knows medicine may be paraphrased to read that one who knows the protean manifestations of hysteria knows the practice of medicine. There is no doubt that much skill, art, knowledge and understanding are necessary for the diagnoses of the neuroses, and in no branch does neglect of general medicine entail more danger to one's reputation or peril to one's patients than in the field of neurology.

An extremely practical rule is not to make a diagnosis of hysteria or other neurosis, or at least exercise great caution, in an individual past forty who has not previously shown out-

spoken neurotic tendencies. It is a fact that most neuroses trace back to early life, and in practically every case one can elicit a history of some neurotic manifestations. The neurosis may blossom forth in adult life, but the soil has long been prepared in adolescence or childhood. The caution is particularly necessary in the case of a neurasthenic syndrome which comes on late in life in a person who has not been a masturbator or one who has not been impotent or never suffered from lack of energy or ambition. In such cases one should rather think of early general paresis, Addison's disease, pernicious anemia, tumor of the brain, malignancy, cerebral arteriosclerosis or some other at first obscure organic disorder. More simple medical conditions occasionally mask under neurotic façades, as the following case will illustrate.

A lawyer of forty-five was referred by his attending physician because of nervousness which had lasted for six months and been precipitated by severe illness in the family. Among the symptoms were sleeplessness, anxiety, tremor, restlessness, and inability to work. Inquiry into the history and personality of the patient revealed a very stable individual who had never been ill. He was happily married, his sex life was normal, his economic condition good, his social relations excellent. The family illness, which was quite disturbing when it happened, fortunately turned out well. It became clear that here was no neurotic soil in which neuroses grow, and yet the picture was that of a neurosis which refused to yield to treatment. The only physical signs present were slight tremor of the extended fingers and an accelerated pulse. Despite the absence of other signs and symptoms of hyperthyroidism the suspicion of its existence, strengthened by what appeared to be substernal dulness, was expressed, and a basal metabolism study as well as x-ray of the chest confirmed the diagnosis. Partial thyroidectomy cured the "neurosis."

Anxiety is such a common symptom that one is frequently tempted, and generally justified, to make a diagnosis of hysteria. But here, too, the rule holds that if it sets in comparatively late in life one should make it with caution. Distinction is made between anxiety neurosis and anxiety hysteria. Both are accompanied by fears of death or insanity, of heart disease or cancer; but in the former the fears are more or less vague, whereas in the latter they are generally quite systematized and may amount to phobias or fears of being alone, riding in trains, etc. The neurotic anxiety is commonly attributed to direct sex frustration, such as, masturbation, coitus interruptus, forced

abstinence or *ejaculatio praecox*. The hysterical anxiety has a more complex psychic structure, frequently occurs apparently unmotivated, and may wake a patient out of sleep. Both are apt to occur in younger persons. The organic condition to be thought of is *angina pectoris* or coronary disease. Naturally these do not occur very often in young persons. The anxiety in heart disease is a rather normal reaction to a very genuine and serious threat. Blood pressure studies, electrocardiograms, the types of accompanying pain, and the whole setting generally serve to make the correct diagnosis. Hyperthyroidism may also be characterized by anxiety, but then there generally are very definite signs pointing to excessive function of the thyroid, such as sweating, *dermographia*, loss of weight, high basal metabolic rate. Difficulties are most likely to arise when an added neurosis masks a real organic condition. So-called "vasovagal crises" deserve passing mention.

While cerebral arteriosclerosis generally occurs past the age of fifty, it may set in much earlier and be characterized by such symptoms as fatigability, mood and other emotional changes, lack of power of concentration, slight lapses of memory, and disturbances in potency or libido—all of which may well pass for a *neurasthenia*. Careful examination, however, will reveal some hypertension, kidney involvement, cardiac enlargement, and peripheral sclerosis, especially of the retinal arteries. Occasionally these signs are lacking, but it is generally well not to make a diagnosis of cerebral arteriosclerosis unless at least some of them are present. To err in either direction and fail to bear in mind these very sound clinical teachings is frequently to court chagrin and sometimes tragedy. Not infrequently a patient is dismissed with the facile remark that there is nothing the matter with him only to learn that he later developed a cerebral thrombosis or hemorrhage or a progressive deterioration ending in dementia.

The early picture of Addison's disease, particularly the fatigue syndrome, may well appear as *neurasthenia*. Very soon, however, the low blood pressure, the diarrhea and the pigmentation of the skin and mucous membranes call attention to the real condition. In the beginning pernicious anemia may deceive the unwary. The loss of appetite, the vague pains, the tongue dysesthesias and other so-called "hypochondriacal"

spoken neurotic tendencies. It is a fact that most neuroses trace back to early life, and in practically every case one can elicit a history of some neurotic manifestations. The neurosis may blossom forth in adult life, but the soil has long been prepared in adolescence or childhood. The caution is particularly necessary in the case of a neurasthenic syndrome which comes on late in life in a person who has not been a masturbator or one who has not been impotent or never suffered from lack of energy or ambition. In such cases one should rather think of early general paresis, Addison's disease, pernicious anemia, tumor of the brain, malignancy, cerebral arteriosclerosis or some other at first obscure organic disorder. More simple medical conditions occasionally mask under neurotic façades, as the following case will illustrate.

A lawyer of forty-five was referred by his attending physician because of nervousness which had lasted for six months and been precipitated by severe illness in the family. Among the symptoms were sleeplessness, anxiety, tremor, restlessness, and inability to work. Inquiry into the history and personality of the patient revealed a very stable individual who had never been ill. He was happily married, his sex life was normal, his economic condition good, his social relations excellent. The family illness, which was quite disturbing when it happened, fortunately turned out well. It became clear that here was no neurotic soil in which neuroses grow, and yet the picture was that of a neurosis which refused to yield to treatment. The only physical signs present were slight tremor of the extended fingers and an accelerated pulse. Despite the absence of other signs and symptoms of hyperthyroidism the suspicion of its existence, strengthened by what appeared to be substernal dulness, was expressed, and a basal metabolism study as well as x-ray of the chest confirmed the diagnosis. Partial thyroidectomy cured the "neurosis."

Anxiety is such a common symptom that one is frequently tempted, and generally justified, to make a diagnosis of hysteria. But here, too, the rule holds that if it sets in comparatively late in life one should make it with caution. Distinction is made between anxiety neurosis and anxiety hysteria. Both are accompanied by fears of death or insanity, of heart disease or cancer; but in the former the fears are more or less vague, whereas in the latter they are generally quite systematized and may amount to phobias or fears of being alone, riding in trains, etc. The neurotic anxiety is commonly attributed to direct sex frustration, such as, masturbation, coitus interruptus, forced

abstinence or *ejaculatio praecox*. The hysterical anxiety has a more complex psychic structure, frequently occurs apparently unmotivated, and may wake a patient out of sleep. Both are apt to occur in younger persons. The organic condition to be thought of is *angina pectoris* or coronary disease. Naturally these do not occur very often in young persons. Difficulties are most likely to arise when an added neurosis masks a real organic condition. So-called "vasovagal crises" deserve passing mention.

While cerebral arteriosclerosis generally occurs past the age of fifty, it may set in much earlier and be characterized by such symptoms as fatigability, mood and other emotional changes, lack of power of concentration, slight lapses of memory, and disturbances in potency or libido—all of which may well pass for a *neurasthenia*. Careful examination, however, will reveal some hypertension, kidney involvement, cardiac enlargement, and peripheral sclerosis, especially of the retinal arteries. Occasionally these signs are lacking, but it is generally well not to make a diagnosis of cerebral arteriosclerosis unless at least some of them are present. To err in either direction and fail to bear in mind these very sound clinical teachings is frequently to court chagrin and sometimes tragedy. Not infrequently a patient is dismissed with the facile remark that there is nothing the matter with him only to learn that he later developed a cerebral thrombosis or hemorrhage or a progressive deterioration ending in dementia.

The early picture of Addison's disease, particularly the fatigue syndrome, may well appear as *neurasthenia*. Very soon, however, the low blood pressure, the diarrhea and the pigmentation of the skin and mucous membranes call attention to the real condition. In the beginning pernicious anemia may deceive the unwary. The loss of appetite, the vague pains, the tongue dysesthesias and other so-called "hypochondriacal"

symptoms, particularly if they occur in women at the menopause age, may well be dismissed as neurotic. So may acroparesthesia with its peculiar sensations in the limbs and the slight vasomotor changes be confused with conversion hysteria.

The possibility of error, perhaps of the greatest import, lies in overlooking the early symptoms of general paresis which so often masks as a neurosis. Here slight memory lapses, imperceptible conduct disorders or undifferentiated moral deviations, lack of will power or ability to concentrate, perhaps a little euphoria or facetiousness alternating with depression and poor judgment, hypochondriacal preoccupation with bodily function, and a host of minor or otherwise insignificant complaints are apt to lead one astray. The fact that spontaneous remissions occur, further adds to the diagnostic difficulties and the possibility of error. Unless a careful history is taken and a meticulous examination made the patient may be told to "forget it," or take a vacation. The danger is all the greater because very early there may be no physical signs, such as pupillary anomalies, finger and perioral tremors, changes in reflexes, or impairment of articulatory speech, and only the positive serology of the blood and spinal fluid can make the diagnosis. In view of the fact that paresis has become a curable disease, oversight in diagnosis is of very grave import. It is worth remarking that occasional danger during the incipient or so-called "neurasthenic" phase of general paresis lies in the possibility that the patient may squander his fortune, offend against sexual and social morality or otherwise infringe on the law. This stage, so frequently overlooked, may very well become forensically important.

The last case cited illustrated the possibility of error in diagnosing hyperthyroidism as psychoneurosis, but in addition to the thyroid other glands of internal secretion may show dysfunction which is not easily recognized. The fact is that in both acute and chronic states of anxiety one may find symptoms simulating early hyperthyroidism, and incipient or advanced Graves' disease may be characterized by a variety of symptoms commonly attributed to the various neuroses. Anxiety, palpitation, tremor, digestive disturbances, occasional fatigue and diarrhea are common to both. Repeated examinations, therefore, and particularly study of the basal metabolic

rate, are as important as intensive psychiatric investigations. Hypothyroidism, too, not necessarily of the grade of myxedema, may be characterized by memory defect, apathy, depression, mental dulness, loss of interest and power of concentration, and digestive disturbances. Impotence may also occur, as it frequently does in hypo- or hyperpituitarism and in gonadal deficiency. I have seen at least 1 case of behavior disorder based on hypophyseal deficiency and cured by pituitary extract. How much ovarian or pituitary-ovarian dysfunction has to do with what passes for menopause neurosis is difficult to say. Certain it is that some correlation exists, even though its nature is not so well known. Occasionally gynergen does cure a menopause neurosis and at times follutein is beneficial. Much less is known of the relationship of the cessation of ovarian function to melancholia, but here too one may suspect, even though one cannot prove, that the two are not unrelated. The point is that endocrinopathies may pass for neuroses and neuroses may mask as endocrinopathies. The same may be said of dysfunction of the vegetative nervous system, though here the relationship is even less well understood. Some day we may learn of the relationship of the function of the hypothalamic region to the neuroses.

In young persons caries of the spine or tuberculous spondylitis may be mistaken for hysteria. It is easy enough to make the diagnosis if there is a gibbus or tenderness of the spinous processes, or if there are signs of compression of the spinal cord, and particularly if an x-ray is taken when bone changes are apt to be pathognomonic even early in the course of the disease. But very early none of these may be present, and the patient may well be dismissed as psychoneurotic. The danger is even greater in case of tumor of the spinal cord. For a long time there may exist only radicular pain, which is diagnosed either as an intercostal neuralgia or atypical sciatica or, worse still, labeled as hysterical. Even the experienced neurologist may err at a time when there are no reflexes changes, no impairment of motor power, no sensory disturbances at the level of the lesion or below it. Unless a spinal tap is done and changes in the spinal fluid are found or evidence of spinal subarachnoid block discovered, or x-ray of the vertebrae gives some clue to the existence of a tumor, it may not only be overlooked but not

even suspected. The diagnosis by exclusion in such cases, when no psychogenic factors are elicited, is particularly fallacious. Such errors are especially apt to occur in the case of latent carcinoma in older patients and of sarcoma in younger ones. The writer remembers particularly the chagrin he and his colleagues felt when after months of fruitless treatment, buffeting about of the patient as an incurable hysteric, and actual neglect, it was finally discovered that the young woman had a sarcoma of the spine which at first compressed roots and merely caused pain without any objective signs and only later compressed the spinal cord by invasion from without. The following case may be of some clinical interest.

A man, forty years of age, was referred for a neuropsychiatric examination because of pains and a host of psychoneurotic symptoms which he had had for years. Of late some of the pains had become more or less constant in the epigastric zone and others radiated to the urinary bladder region. There was something paroxysmal about the pains but otherwise they lacked special characteristics. Between treatments for a psychoneurosis, which he may have had, gastro-intestinal studies and investigations of the genito-urinary system were made, with negative results. The pains persisted and increased, but occasionally remitted as well, so that the diagnosis of psychoneurosis was maintained, all the more as the general findings thus far had been negative. Unfortunately there were no neurologic signs, and so the diagnosis was concurred in and no further effort made to study the case. A very grave error of omission, as it later turned out, was the failure to advise lumbar puncture. The patient finally did begin to show impairment of motor power in the legs, increase of deep reflexes, sensory disturbances, and urinary difficulties. This time a lumbar tap showed xanthochromic fluid, increased protein, and spinal subarachnoid block on manometric testing. Fortunately an extradural spinal cord tumor was removed and the patient recovered. Obviously, there is no reason why a psychoneurotic may not develop a cord tumor and none why one should permit the psychoneurotic symptoms to obscure an organic condition. It is of passing interest that many, though not all, of the neurotic symptoms vanished with the removal of the tumor.

Tumor of the brain, more particularly of the so-called "silent areas," may for a long time fail to give rise to violent headache, dizziness, vomiting, choked disk, or focal signs. Tumors of the frontal lobes may be characterized by symptoms which are commonly regarded as psychoneurotic. Some of them may be so exquisite as to simulate typical hysteria or obsessional neurosis, though they are more likely to appear as psychiatric manifestations of organic brain disease. I have

seen one instance in which the symptoms of a neurosis were so pronounced that the patient was psychoanalyzed for months. The error here consisted in the failure to look with suspicion on the persistence of a monosymptomatic neurosis and to re-examine the patient physically from time to time. There were extenuating circumstances, but the fact is that a quadrantic hemianopic field defect led both to the suspicion and the localization of a deep-seated temporal lobe glioma. Similar tragic errors have occurred before and are likely to occur again; in the case under discussion the error was softened by the fact that the tumor was irremovable from the very beginning. The rule may be laid down, however, that whenever there is the slightest suspicion of brain tumor encephalographic air studies should be made; the difficulty is that in cases when the diagnosis of psychoneurosis is made, tumor is not likely to be suspected. In such cases only repeated examinations can obviate errors.

In its early stage multiple sclerosis may possibly be confused with hysteria. Both occur in the comparatively young, remissions are common to both, and so are emotional disturbances, particularly euphoria and unmotivated laughter. However, definite organic signs characterize the first and their absence the second. Inequality of deep reflexes, absent abdominals, nystagmus, ataxia, a Babinski sign, speech disturbances, and pallor of the optic disks, are never seen in hysteria, whereas some or all of them characterize disseminated sclerosis. On the other hand, psychogenic factors are entirely lacking in the organic diseases and are written all over the hysterical symptomatology. Yet all of these criteria may fail one, as shown by a recent case which for ten or more years was treated for hysteria by several competent neurologists only to be ultimately recognized as a definite organic disease.

The subject of headache is altogether too vast to be dealt with in a brief discussion on differential diagnosis. Actually, because of the subjective nature of the symptom, there is no way of telling a hysterical headache from one based on organic disease, if for no other reason than the fact that the ultimate physiology of headaches is not well understood. Furthermore, it is difficult to tell, for instance, a so-called "toxic headache" or one following head trauma without accompanying objective signs of brain damage from a psychogenic one. Generally

speaking the psychogenic headache is more of a pain in the head or scalp, one frequently characterized by a variety of adjectives. Somehow the hysteric does not give the impression of true suffering, and occasionally a smile betrays the fact that the pain is not quite so unendurable as the meticulous description intends to convey. Migrainous or paroxysmal headaches, which are so frequently atypical, may well lead to diagnostic errors. Not all begin early in life, not all are periodic, limited to one side or followed by nausea or vomiting, a heredity history is not always present, and psychic factors may precipitate a migrainous attack. Both kinds are by far more common in women. The final diagnostic criterion, therefore, is the presence of definite psychogenic factors which account not only for the headache but for the numerous other hysterical symptoms which generally coexist.

While the diagnosis of hystero-epilepsy has been pretty generally discarded there are instances where it is difficult to tell between hysterical syncope and epileptic loss of consciousness. This much is true, however, that there never is loss of the pupillary light reflex in hysteria, there is not that absolute amnesia for the attack and there is not quite true coma. Rarely does the hysteric injure himself in falling, and true tongue biting, frothing, and incontinence also do not occur in hysteria. Postepileptic confusional states or epileptic furor may be mistaken for hysterical fugues, but here again there is absolute amnesia, one frequently elicits a history of convulsions, and the paroxysm is apt to be much briefer. The correct diagnosis is of extreme importance from a medicolegal point of view, as epileptics have been known to commit acts of violence up to murder during seizures characterized by furor. Finally, it is well to remember that the hysterical attack is practically always psychologically motivated; the epileptic one comes unheralded.

The question of so-called "hysterical tics" and spasms and chorea or other dyskinesias may be briefly dismissed with the statement that most of them are not hysterical at all. This is contrary to the old teaching, but if epidemic encephalitis taught anything it was to the effect that most of the dyskinesias can and do have an organic basis and that other organic signs may be entirely lacking. In any case hysterical chorea is a mis-

nomer; a movement is either choreic or hysterical. Tics are mostly organic, but if they are psychogenic they are more likely compulsive phenomena. Torticollis probably always is organic, and very likely a fragment of dystonia. Neither myoclonus nor athetosis is hysterical. It is a fact, though, that most of the dyskinesias, especially dystonia musculorum deformans, are at first diagnosed as hysterias.

In the case of occupational neuroses, it is well first to rule out such organic diseases as neuritis, tabes and syringomyelia or such symptoms as dystonia, astereognosis and apraxia. One should look very carefully for changes in reflexes, fibrillations, atrophies, sensory disturbances and responses to electrical testing. The nature of the occupation and the presence of psychogenic factors do not always decide, but they are of considerable help.

Finally, a word about hysterical pains sometimes known as "psychalgias." In a recent paper<sup>1</sup> on abdominal pain as the result of brain disease I showed that such pains do occur and that they are generally overlooked. It is a matter of common experience to see patients operated upon for "gastric ulcer, gallstones, appendicitis, etc.," which they never had. It is equally true that abdominal pain alone or associated with gastric or duodenal ulcer can occur on the basis of organic brain disease, especially tumors. While it is not known whether involvement of the cortex, the subthalamie region or the vagus center is responsible for the abdominal syndrome, the mediation of the impulses must be via those structures. The question, therefore, arises whether so-called "hysterical pains," especially abdominal, are not in effect the result of disturbed brain physiology and whether the dismissal of a patient with the cavalier statement that "he is a belly-acher" is not only bad psychology but poor physiology and worse medicine.

## CLINIC OF DR. CLAUDE EDWIN HEATON

FROM THE OBSTETRICAL AND GYNECOLOGICAL SERVICE, BELLEVUE HOSPITAL AND NEW YORK UNIVERSITY COLLEGE OF MEDICINE

---

### PRENATAL CARE

PRENATAL care is complete medical supervision of the pregnant woman. The aim is preventive rather than restorative, a purpose well within the scope of every conscientious practitioner.

Antepartum supervision unquestionably plays an important rôle in preserving the health of both mother and baby. The maternal mortality rate, the incidence of stillbirths and neonatal deaths are influenced by adequate care during pregnancy. Furthermore, we believe that a relationship could be shown between antepartum care and the quality and results of service at delivery. Admittedly lack of skill and judgment during labor may offset the good effects of such care. Then, too, an occasional bad outcome is probably inevitable as the result of obstetric accident or emergency. Nevertheless to bring the expectant mother to delivery in the best possible health, and for the attendant to be armed in advance with a knowledge of all possible complicating factors, would seem to be a valuable advantage.

Superficial and perfunctory care during pregnancy may, however, be worse than none at all, for as Munro Kerr points out both doctor and patient are given a false sense of security. Adequate supervision implies much more than casual advice about some minor disorder or an occasional examination of the blood pressure and urine. An early determination of the exact physical status of the patient is implied. Application of a knowledge of the nutritional aspects of pregnancy, the prevention of anemia, prompt detection and treatment of toxemia, the early diagnosis and control of syphilis, the discovery and correction of malposition, and an appraisal of the relation of

birth passage to passenger—all these are implied in adequate prenatal care. A broad application of the accepted standards of prenatal care requires a medically trained person; as DeLee has stressed, it means raising the plane of obstetric care.

The expectant mother should consult her physician as soon as a menstrual period has been skipped. A tentative diagnosis of pregnancy may usually be made on the basis of presumptive signs and symptoms. Biologic tests for pregnancy are seldom indicated since extra expense is incurred for information which a short lapse of time makes obvious. During the early, so-called "negative phase" of gestation more frequent visits to the doctor than is usually customary are of advantage, in enlisting the patient's interest and establishing confidence. Many minor ills are anticipated and prevented in the first few weeks.

By a thorough general history and physical examination intercurrent or associated conditions inimical to pregnancy are discovered. Inquiry is made concerning a past history of scarlet fever, diphtheria, pneumonia, rheumatic fever, recurrent attacks of tonsillitis, kidney disease and heart disease. The history of past surgical procedures are noted, especially operations involving the pelvic organs since certain types of suspension of the uterus or amputation of the cervix may produce difficult labor.

The patient's present status is recorded as regards appetite, sleep, bowels, urination and average weight. Concerning the menstrual history the physician wishes to know about the regularity, frequency, duration, amount and possible associated pain. From the date of the last menstrual period the probable date of confinement is estimated by adding seven days to the first day of the last period and counting back three months. The expectant mother should be firmly impressed with the fact that the exact date the baby is due cannot be estimated—that variations of two weeks either way may be expected and looked upon as normal. With a history of previous pregnancies, inquiry should be made as to the prenatal period, labor and puerperium, type of labor, mode of termination, size and condition of the baby. All possible information helpful in the present situation should be sought.

The following medical conditions are often complicated by pregnancy: (1) organic heart disease, (2) tuberculosis, (3)

chronic nephritis, (4) diabetes, (5) thyroid disturbance. Pregnancy found associated with the above should always be looked upon as the secondary or complicating condition. The problem of intercurrent conditions should be approached from the standpoint of internal medicine. Individualization is always necessary, with consideration of all factors, mental and environmental, in a given case. Here indeed the physician is reminded of the Hippocratic aphorism that experience is fallacious and judgment difficult.

While not within the scope of this paper to enter into the details of the management of these associated conditions in pregnancy, a brief comment about each in relation to prenatal care seems in order. Early discovery is in itself of the utmost value, enabling the physician to consider the advisability of interruption of pregnancy at the most opportune time or to institute appropriate treatment without delay. E. Allen and A. P. Bauer believe that future statistical studies of maternal and fetal deaths should include a critical analysis of the patient's health as a great factor in the obstetric end-results rather than basing conclusions entirely on the outcome of surgical obstetric procedures.

**Organic Heart Disease.**—Patients with organic heart disease belonging to Classes I and IIA generally do well during pregnancy. With a history of previous congestive failure or with failure early in pregnancy, the mother would seem to be running an unjustifiable risk. The treatment of decompensation is the same as in the nonpregnant. No attempt is made at surgical intervention during the acute attack. The cooperation of a cardiologist is essential.

**Tuberculosis.**—A wide diversity of views are found concerning all phases of the problem of tuberculosis complicated by pregnancy. General agreement exists that prior to the third month of pregnancy, a woman with active tuberculosis should be interrupted. If tuberculosis is discovered after the third month pregnancy should be allowed to continue. The value of collapse therapy when indicated and of sanatorium treatment are stressed by many authorities.

**Chronic Nephritis.**—Diagnosis is difficult and may be impossible during pregnancy. The condition is rare. Evidence of kidney damage must be sought for by repeated kidney func-

tion tests. Of these the renal concentration test, the phenol-sulfonphthalein test, and the urea clearance test are accepted as the most valuable. Blood chemistry examination for possible nitrogen retention and study of the eyegrounds for retinitis should be done. While the accepted treatment is interruption at any stage at which diagnosis is made, this is not always possible in the individual case.

**Diabetes.**—Since the insulin era there has been an increase in the number of diabetics bearing children. Glycosuria in pregnancy may be due to dextrose or lactose. True diabetes should be ruled out by blood sugar determinations and sugar tolerance tests. Control of the disease by proper diet and the careful use of insulin necessitates close supervision throughout pregnancy. The diabetic is prone to preeclampsia creating a grave problem. A knowledge of dietetics and of insulin therapy is required to protect the patient against acidosis, glycogen depletion and hypoglycemia. The usual diet should be given as regards providing mineral elements and vitamins. From 150 to 300 Gm. of carbohydrates should be taken. Control by urinalysis and blood sugar estimations should be carried out with increasing frequency in the last weeks of pregnancy. Frequent small doses of insulin are preferable to infrequent large doses.

**Thyroid Disease.**—Normally there occurs a physiologic increase in the basal metabolic rate reaching a maximum of 20 per cent in the last trimester. The work of Litzenberg and Cary indicates that with a low basal metabolism in early pregnancy, thyroid medication may prevent abortion. There seems to be a subjective improvement in patients with a low metabolic rate where small doses of thyroid are given in conjunction with hygienic measures.

Hyperthyroidism is a rare condition in pregnancy—interruption is not indicated. Mental rest, that is freedom from worry, fear and strain, as well as physical rest is important. Sedatives should be prescribed in conjunction with the administration of iodine in the form of Lugol's solution.

**Obstetric Examination.**—The unreliability of external measurements of the pelvis is generally conceded. Thoms among others having pointed out the inadequacy of external pelvimetry. However, with this in mind the interspinous and

the intercrystal measurements and the external conjugate should be recorded. An external conjugate below 18 cm. generally indicates contraction at the inlet; a normal external conjugate may be present, however, in a poor pelvis.

Vaginal examination is indicated at the first prenatal visit for the diagnosis of pregnancy, to determine the position of the uterus, the possible presence of fibroids or ovarian cysts or infection in the lower generative tract. Smears are taken from the urethra and cervix only as indicated.

No attempt is made to treat the retroverted pregnant uterus by manual replacement or pessary. The patient is instructed how to take the knee-chest position and advised to sleep on her abdomen.

Internal pelvimetry is of great value in estimating the capacity of the pelvis. If the promontory is felt, the diagonal conjugate is measured and 2 cm. subtracted to obtain the true conjugate. Note whether the sacrum curves well back. Palpate the spines and estimate the length of the sacrospinous ligaments. If well over 2 fingers the sacrosciatic notch is probably wide—a narrow notch indicates an android type of inlet. The slope of the side walls can be noted and the width and length of the pubic arch. Findings should be rechecked at the seventh month.

**Hygiene of Pregnancy.**—This includes consideration of the nutritional aspects of pregnancy, rest and exercise, bowel hygiene, care of the teeth—in fact, all aspects of the mother's way of living which influence health.

The influence of food on child-bearing has received increasing recognition. The dietary management of pregnancy requires precise instruction and the correction of current misconceptions. A well-balanced optimal diet rather than a merely adequate one is indicated.

The expectant mother should be impressed with the fact that the following basic daily diet is absolutely necessary:

- 1 quart of milk.
- Fresh and cooked fruit.
- 1 cooked green vegetable.
- 1 raw green vegetable.
- 1 egg.
- Lean meat including red meats, and liver once a week.
- Cereal.

tion tests. Of these the renal concentration test, the phenol-sulfonphthalein test, and the urea clearance test are accepted as the most valuable. Blood chemistry examination for possible nitrogen retention and study of the eyegrounds for retinitis should be done. While the accepted treatment is interruption at any stage at which diagnosis is made, this is not always possible in the individual case.

**Diabetes.**—Since the insulin era there has been an increase in the number of diabetics bearing children. Glycosuria in pregnancy may be due to dextrose or lactose. True diabetes should be ruled out by blood sugar determinations and sugar tolerance tests. The usual diet should be given as regards providing mineral elements and vitamins. From 150 to 300 Gm. of carbohydrates should be taken. Control by urinalysis and blood sugar estimations should be carried out with increasing frequency in the last weeks of pregnancy. Frequent small doses of insulin are preferable to infrequent large doses.

**Thyroid Disease.**—Normally there occurs a physiologic increase in the basal metabolic rate reaching a maximum of 20 per cent in the last trimester. The work of Litzenberg and Cary indicates that with a low basal metabolism in early pregnancy, thyroid medication may prevent abortion. There seems to be a subjective improvement in patients with a low metabolic rate where small doses of thyroid are given in conjunction with hygienic measures.

Hyperthyroidism is a rare condition in pregnancy—interruption is not indicated. Mental rest, that is freedom from worry, fear and strain, as well as physical rest is important. Sedatives should be prescribed in conjunction with the administration of iodine in the form of Lugol's solution.

**Obstetric Examination.**—The unreliability of external measurements of the pelvis is generally conceded. Thoms among others having pointed out the inadequacy of external pelvimetry. However, with this in mind the interspinous and

the intercrystal measurements and the external conjugate should be recorded. An external conjugate below 18 cm. generally indicates contraction at the inlet; a normal external conjugate may be present, however, in a poor pelvis.

Vaginal examination is indicated at the first prenatal visit for the diagnosis of pregnancy, to determine the position of the uterus, the possible presence of fibroids or ovarian cysts or infection in the lower generative tract. Smears are taken from the urethra and cervix only as indicated.

No attempt is made to treat the retroverted pregnant uterus by manual replacement or pessary. The patient is instructed how to take the knee-chest position and advised to sleep on her abdomen.

Internal pelvimetry is of great value in estimating the capacity of the pelvis. If the promontory is felt, the diagonal conjugate is measured and 2 cm. subtracted to obtain the true conjugate. Note whether the sacrum curves well back. Palpate the spines and estimate the length of the sacrospinous ligaments. If well over 2 fingers the sacrosciatic notch is probably wide—a narrow notch indicates an android type of inlet. The slope of the side walls can be noted and the width and length of the pubic arch. Findings should be rechecked at the seventh month.

**Hygiene of Pregnancy.**—This includes consideration of the nutritional aspects of pregnancy, rest and exercise, bowel hygiene, care of the teeth—in fact, all aspects of the mother's way of living which influence health.

The influence of food on child-bearing has received increasing recognition. The dietary management of pregnancy requires precise instruction and the correction of current misconceptions. A well-balanced optimal diet rather than a merely adequate one is indicated.

The expectant mother should be impressed with the fact that the following basic daily diet is absolutely necessary:

- 1 quart of milk.
- Fresh and cooked fruit.
- 1 cooked green vegetable.
- 1 raw green vegetable.
- 1 egg.
- Lean meat including red meats, and liver once a week.
- Cereal.

The caloric requirements of pregnancy are met by an intake of 2400 to 3000 calories. The above basic diet furnishes at least 1000 calories. The patient who is underweight at the beginning of pregnancy may require up to 4000 calories. The overweight patient should not reduce during pregnancy, but minimal gains are made on a 2000 caloric diet. No attempt is made to control the weight of the baby by diet since even were this possible it would be inadvisable because of the danger of depriving both mother and fetus of essential foodstuffs. The total weight gain during pregnancy should be 20 to 25 pounds. In the last trimester of pregnancy the gain should be limited to around 1 pound a week.

Formerly it was customary to restrict nitrogenous foods—indeed “no meat, no fish, no eggs” was a common slogan taught the expectant mother. The pregnant woman needs around 100 Gm. of protein daily. Meat, eggs and milk contain proteins of high biologic value, that is, containing the amino-acids essential for growth and maintenance. Strauss believes that restricted dietary intake of protein in pregnancy is harmful and that no injurious consequences follow administration of diets high in protein to women with toxemia of pregnancy.

The mineral requirements are best met by the intake of 1 quart of milk daily, assuring an intake of 1.2 Gm. of calcium and 0.9 Gm. of phosphorus. Vitamin D has a definite effect on calcium and phosphorus absorption, therefore if the patient is unable to take milk, dicalcium phosphate may be prescribed with viosterol. In addition to milk the use of fruits and green vegetables should assure an adequate supply of vitamins. A diet containing a sufficient amount of these so-called “protective foods” is the main essential. The protection of the mother’s bones and teeth, the avoidance of certain minor disorders such as subcutaneous edema, itching, paresthesias, and cramps in the calves of the legs, are dependent upon calcium and certain vitamins notably D. An adequate diet is also the best preventive of anemia during pregnancy. Iron, calcium and vitamin preparations are best prescribed only on indication.

In many of the handbooks for mothers the advice is given to drink 8 glasses of water daily. Arnold has pointed out the importance of controlling the fluid balance during pregnancy

in preventing severe toxemia. Patients with a past history of hypertensive vascular disease or with signs of incipient pre-eclampsia as evidenced by a slow, steady rise in the diastolic pressure should be taught to measure their fluid output and regulate the intake in accordance. One should not wait for frank edema to start balancing intake and output.

**Anemia.**—Determination of the presence of anemia is a part of prenatal care. At least one routine blood count and hemoglobin estimate at the seventh month would seem a wise procedure. Given an environment with insufficient diet, poor hygienic surroundings, lack of sunshine and outdoor exercise, and frequent acute infections, we may expect to find anemia of varying degree. Anemia in pregnancy falls into three groups. The so-called "physiologic hydremic anemia" is not a true anemia and should not be confused with simple nutritional anemias of mild degree which are common. The second group comprises the hypochromic microcytic anemia—a more severe form in which dietary deficiency plus disturbed gastric secretion are responsible. Reduced iron, 90 grains daily in small capsules, should be given in combination with liver therapy. The third type of anemia, the macrocytic, addisonian type, is very uncommon. Liver therapy supplemented by iron is used. In all severe anemias repeated small blood transfusions are of great value.

**Vomiting of Pregnancy.**—In the early weeks of gestation attempt should be made to prevent morning sickness and possibly the development of the severe form of hyperemesis by dietary means combined with psychotherapy. Six small meals a day should be eaten. Vitamin requirements should be met by plenty of the protective foodstuffs. Mineral waters and ginger ale are helpful. Hard candies supply much needed sugar. Constipation is corrected. If in spite of these measures vomiting persists, phenobarbital  $\frac{1}{2}$  grain, three times a day, is prescribed. Severe persistent vomiting demands more stringent treatment. Do not wait for dehydration, acetonuria and increased pulse rate before hospitalization.

**Dental Care.**—An early visit to the dentist in order that he may clear up possible foci of infection is necessary. There is apparently no greater tendency to dental caries during pregnancy than at any other time. Dental treatment and opera-

tions may be safely carried out at any time in the prenatal period.

**Antepartum Bleeding.**—Abortion is the chief cause of antepartum bleeding during the first two trimesters. The writer is skeptical as to the possibility of preventing spontaneous abortions by prenatal care because he believes that these are due in many cases to defects inherent in the ovum itself. The time to combat habitual abortion is preconceptional with attention to the health of both marital partners and the endocrine status of the woman. However, the use of progesterone in the early weeks of pregnancy is worth trying where abortion may be due to faulty implantation.

During the last trimester bleeding accompanied by pain points to premature separation of the placenta. Painless bleeding, no matter how trivial, should arouse suspicion of placenta praevia and requires that it should be ruled out. The patient should be placed in a hospital, her blood typed and a donor made available. In the interest of the baby internal examination should be deferred since manipulation may precipitate severe hemorrhage. If the presenting part seems deeply engaged placenta praevia may be ruled out although low implantation must still be considered. Where the presenting part is movable well above the symphysis the probabilities are that the placenta is implanted below it.  $\alpha$ -Ray will sometimes reveal the true situation.

**Syphilis.**—We wish to stress the importance of a routine Wassermann test early in pregnancy in private practice. Congenital syphilis is practically a preventable disease. The incidence of positive Wassermann reactions among private patients is probably less than 2 per cent. In a large percentage of prenatal patients with syphilis the disease is latent with no signs or symptoms helpful in diagnosis. While treatment should be started as early in pregnancy as possible still, as Speiser states, it is never too late in pregnancy to derive some benefit by treatment as far as the offspring is concerned.

**Toxemia.**—Early detection and treatment of preeclampsia is perhaps the chief reason for regular and frequent prenatal visits at which time the weight, blood pressure, and urinalysis are recorded. A sudden gain in weight due to water retention may be the first warning of toxemia. A rise in blood pressure

above 140 should immediately be heeded. To a certain extent the degree of hypertension is proportionate to the toxemia; this is also true as regards proteinuria. Prenatal care cannot be considered adequate where in the presence of rising blood pressure and increasing proteinuria prompt treatment is not instituted since in the majority of cases by conservative means the patient may be carried to or near term with a favorable outcome.

Hospitalization is usually required to secure adequate bed rest, and to study the possibility of renal impairment. Sedation with bromides, 15 grains, or phenobarbital,  $\frac{1}{2}$  grain three times a day, is useful. Record is kept of the urinary output and the intake of fluids restricted in the mild cases to two thirds the previous day's output. In the presence of marked edema no fluids are given for the first twenty-four hours. Sodium salts are restricted but proteins are given,  $\frac{2}{3}$  to 1 Gm. per kilo body weight. One hundred cc. of 50 per cent solution of glucose are given intravenously and repeated every four hours as indicated. Intravenous magnesium sulfate, 20 cc. of 10 per cent solution repeated as indicated, may also be given in the more severe cases.

If, after rest, sedation, dietary restriction, elimination, intravenous hypertonic glucose and magnesium sulfate, the patient's condition remains unimproved or becomes worse, the problem of interruption arises. A persistently high diastolic pressure is evidence of angiospasm. Examination of the eye-grounds for evidence of angiospastic lesions of the retinal arterioles is helpful. Note whether the reflexes are hyperactive. There is considerable evidence that to allow the severely toxic pregnant woman to go on is to allow permanent damage to her cardiovascular renal system. Induction with delivery from below is the method of choice in those cases, especially multiparae near term, with favorable soft parts. Otherwise, cesarean section performed under local anesthesia is the procedure of choice. Inhalation anesthesia should not be used with the possible exception of cyclopropane.

**Eclampsia.**—Every pregnant woman is a potential eclamptic. We aim to prevent the severely toxic patient from going on to the convulsive stage. This is not always possible even with adequate prenatal supervision since fulminating cases do

occur. Even here it is an open question whether with closer watch and better cooperation on the part of the patient the convulsive stage might not be reached. The patient with convulsions should be treated by conservative methods. Forcible delivery from below or cesarean sections are contraindicated because of the poor results. The patient should be in a dark room, kept quiet, morphine given and also intravenous glucose and magnesium sulfate. Gastric lavage, hot packs, and colonic irrigations are no longer used. When the disease has been controlled interruption may be considered.

**Disproportion and Malposition.**—Beginning with the fifth month the patient should be “tabled” for abdominal examination at each visit. Perhaps no procedure is of more value than inspection, palpation, auscultation and mensuration of the abdomen and every opportunity should be sought to become familiar with this simple technic. The height of the fundus is measured with a pelvimeter and recorded. The fundus reaches 29 cm. and then drops slightly at term, especially in primiparae. The McDonald measurement taken with a tape is another useful procedure. One end of the tape is placed at the upper border of the symphysis while the other is held by the thumb in the palm of the hand. The fingers or the upper hand are held at right angles to the fundus of the uterus, and the tape follows the contours of the uterus except at the upper border where the fingers make a tangent to the tape. After the sixth month this measurement divided by 3.5 gives the duration of pregnancy in lunar months—at term it is 35 cm. and the fetus is of average size. A measurement above 35 cm. suggests a large baby, hydramnios or twins.

Examination of the abdomen at each visit should reveal an abnormal position of the baby. Studdiford believes that with improvement in antepartum diagnosis and with routine use of external cephalic version in all suitable cases, the gross mortality of breech delivery would be reduced greatly. External version is contraindicated in multiple pregnancy and placenta praevia. The baby usually remains a vertex after turning which is performed on or after the seventh month. Repeated attempts should be made. The rather rare but dangerous transverse presentation may also be corrected but has a tendency to recur.

At the seventh month a careful internal examination is indicated to recheck the pelvis. The problem of disproportion looms in every labor—will the head come through? Failure to recognize the presence of grave pelvic deformity in a case which terminates fatally after a prolonged labor is a sad outcome which in some cases at least must be considered due to poor prenatal care.

As the abdominal examination is repeated each weekly visit in the last month, the physician looks for evidence of disproportion. A distorted pelvis is rare and easily recognized. The head may be deeply engaged or dipping well into the brim so that it is fixed. If the head is freely movable from side to side above the brim one should be on guard. The head may be high merely because of excessive fluid or unretracted lower uterine segment. Can the head be pushed into the inlet by gentle pressure on the fundus? Is there overriding and a pendulous abdomen? Where doubt exists as to the actual situation one should resort to x-ray and consultation.

**x-Ray.**—Roentgenography is a valuable aid in obstetric diagnosis. It will reveal the presence of twins, abnormalities of the fetus, such as anencephalus, and gives information as to position and presentation. It is being used in the diagnosis of placenta praevia.

Roentgen pelvimetry deserves wider use in prenatal work. There are various methods now in general use. An example of the frame (positions) method is the centimeter grid procedure of Thoms which gives a clear idea of the size and shape of the inlet. Study of the inlet by whatever method used should always be supplemented by a lateral view of the pelvis and by a view of the outlet. There is a tendency to consider disproportion as a problem of the inlet alone; it does not always follow that because the inlet is ample, serious difficulty will not be encountered at the lower levels. The lateral view is valuable in showing the relation of the presenting part to the birth passage. The true conjugate may be measured, the shape and position of the sacrum studied and the type of notch. All x-rays of the pelvis are more useful the nearer the patient is to term.

At Bellevue Hospital we have been particularly impressed with the advantages of the Caldwell and Moloy method of

stereoroentgenography for the study of the pelvic architecture. The method is useful even where the precision stereoscope is not available. By x-ray study of the pelvis elective cesarean section may be determined upon in advance in a small number of cases where absolute disproportion is found to exist. The majority of cases will be found to have ample pelvises but a knowledge of the shape of the pelvis has proved a valuable aid in the clinical conduct of the case. To obtain this knowledge antepartum is to bring one more factor influencing the outcome into the realm of certainty. The size of the baby as a factor in disproportion also needs consideration. Exact cephalometry is not required. Either the lateral view or stereoscopic plates taken near term give a clear idea of the relation of the fetal head to the birth canal. The physician may now await the onset of labor with equanimity although at least two unknown factors still remain—the possibility of prolapsed cord and the possibility of functional or soft part dystocia. Finally the question of induction of labor arises during the course of prenatal supervision. No matter how simple the method used, induction carries with it special risks. Therefore, the indications should be clean cut and urgent. Never should it be done as a mere matter of convenience or because of importunity. Induction has never found favor in this country as a method of treatment for contracted pelvises.

Where home delivery is contemplated the patient should be advised concerning the necessary supplies and preparations. All patients should be instructed as to the signs of beginning labor and advised to report immediately the onset of any pains, or the passage of fluid or blood.

In conclusion, we believe:

1. That prenatal care implies constant and efficient supervision with hospitalization for those conditions too serious to be adequately coped with at home.
2. That the diagnosis and management of intercurrent or associated conditions complicated by pregnancy necessitate individualization and the aid of internal medicine.
3. That the nutritional aspects of pregnancy deserve consideration in the prevention of deficiency states.
4. That congenital syphilis is a preventable disease.
5. That effort should be made to prevent eclampsia by

prompt attention to signs of hypertensive vascular disease evidenced by a progressive rise of the diastolic blood pressure, proteinuria, upset water balance and spastic changes in the retinal arterioles.

6. That antepartum bleeding necessitates ruling out placenta praevia.

7. That malposition, especially breech, should be corrected where possible.

8. That the relative size of the birth canal and passenger should be determined in advance for possible disproportion and that roentgenography should be utilized.

9. That the physician who realizes he has two lives confided to his care will approach the privilege of prenatal supervision of expectant mothers as the biggest job in preventive medicine he now has to do.

DANGERS OF DEHYDRATION TREATMENT IN  
HEART DISEASE

IN this paper the authors propose to consider certain untoward effects of diuresis and dehydration therapy with suggestions for their prevention and treatment. Because of their remarkable efficiency, mercurial diuretics will receive special consideration although this discussion would pertain with equal force to other potent diuretic agents.

It has long been realized that elimination of excess fluid from the body tissues is in itself a distinct aid to cardiovascular efficiency, producing both subjective and objective improvement. The mechanism of this change has been the subject of considerable investigation. It may be due in part to a diminution in peripheral resistance and to a transient decrease in blood volume, which has been definitely shown to occur.<sup>24</sup> Friedman and his associates<sup>1</sup> attribute the improvement to: (1) a decrease in the load of the heart; effected by producing a decrease in the flow of blood through edematous tissues in proportion to the metabolism, the resulting decline in venous return and in venous pressure tending to decrease the cardiac output; (2) an increase in the ability of the heart to carry the load by reducing myocardial edema and thus increasing the contractile power of the heart.

Not infrequently the diuretic effect of the xanthines and even of the "sheet-anchor" of cardiac failure—digitalis—is disappointing. In 1920, a new and potent diuretic drug was added to the therapeutic armamentarium. Saxl and Heilig<sup>2</sup>, employing novasurol (merbaphen), an organic mercurial com-

pound, in the treatment of luetic aortic disease found that drug produced remarkable diuresis in decompensated cases. When, in 1924, Keith and his associates<sup>4</sup> reported the utility of calcium chloride in diuretic therapy of nephritis the study of dehydration received another impetus.

The new mercurial compound, novasurol (merbaphen), was widely hailed and extensively utilized. A series of related drugs—salyrgan (mersalyl), novurit, neptal, mercupurin—was rapidly developed and used with satisfaction. These drugs are so superior to any of their predecessors that any discussion of untoward effects of dehydration must involve a discussion of their action, although, as already indicated, any effective diuretic could produce similar results.

As experience accumulated, certain undesirable effects of the mercurial compounds were observed. These may be classified as follows:

1. Fatality shortly after the administration of the drug.
2. Local tissue necrosis, phlebitis, neuritis.
3. Symptoms of mercurialism.
4. Purpura.
5. The syndrome of restlessness, mental confusion, apathy, coma, and—in some instances—death.
6. Combinations of 3 and 5 as occurred in one of our cases.

Rapid fatality<sup>5, 6, 7</sup> is interpreted as idiosyncratic<sup>6</sup> anaphylactoid, as a "speed shock" phenomenon<sup>8</sup> or possibly as due to cardiovascular collapse as seen in adrenalin poisoning (see the Discussion of Jackson's work<sup>9</sup> on the pharmacology of the mercurial diuretics). The best safeguard against this type of accident is slow injection when the intravenous route is used. Local tissue damage is avoided by accurate placement of the drug in vein or muscle when these routes are used. Symptoms of mercurialism occur very occasionally.<sup>10, 11, 12</sup> Since the use of the mercurial diuretics is usually characterized by a "thrust excretion" the drugs are rapidly eliminated except when they fail to act efficiently. In other words, the danger of mercurialism probably varies inversely with the degree of diuresis and the two are to a certain extent mutually exclusive. Nevertheless, it should be remarked that when the first injection is unsuccessful a second may safely be administered after forty-eight hours. Symptoms of mercurialism have been reported

with salyrgan by Rosenthal,<sup>11</sup> necropsy revealing colitis, tubular nephritis and, in addition, pulmonary embolization. Similar findings were recorded by Snell and Rowntree<sup>12</sup> in their paper on purpura following the use of mercurial diuretics. The syndrome of restlessness, mental confusion, apathy, and coma is the most serious complication of dehydration therapy and is the one with which this paper is concerned. It has been previously described by the authors<sup>13</sup> and other writers.<sup>14, 15, 16</sup>

It is important to reiterate that no indictment of the mercurial diuretics is intended. These drugs are indispensable in the treatment of many varieties of water retention and their value cannot be overestimated. However, we propose to outline certain methods by which they may be used with even greater safety than heretofore. To do this, it will be necessary to consider briefly the pathologic physiology of dehydration in general, the pharmacology of certain diuretics and especially of the mercurials, the contraindications to severe dehydration therapy, the syndrome of excessive dehydration, the antidotal measures to be employed if dangerous symptoms supervene.

#### PATHOLOGIC PHYSIOLOGY OF DEHYDRATION

Examples of untoward effects of dehydration are found in a wide variety of pathologic states in which salts and water are lost from the body. The algid form of cholera<sup>17</sup> and the alimentary intoxication of infants are examples. The prime importance of water and salt depletion in the latter condition has been clearly demonstrated by the admirable work of Karelitz and Schick<sup>18</sup> who have shown that the restoration of water and salts (together with transfusion) is often life saving. It is obvious then that untoward effects of dehydration may be observed in cases in which no diuretic therapy is used.

While a number of different ions are present in the body cells and fluids, it is well established that sodium is the most important for holding water in the intercellular tissue spaces<sup>19</sup> and that it plays an extremely important rôle in the hydrodynamics of the body. With loss or gain of fluid there is a corresponding loss or gain of sodium. Consequently, although the other ions may be of some importance in water metabolism it is sodium and water particularly which have a particular bearing on the syndrome emphasized in the present article.

## PHARMACOLOGY OF DIURESIS AND DIURETICS IN GENERAL

Diuresis in general<sup>20</sup> is characterized by loss of water and of cations in the proportion in which they occur in blood plasma and extracellular fluids; *i. e.*, 145 milliequivalents of sodium, 4 milliequivalents of potassium and 4 milliequivalents of calcium per liter. Chloride is excreted in larger amounts than the basic ions, *i. e.*, 190 milliequivalents. The greater the diuresis, the longer is the time required by the body to regain its fluid. The larger the subject, *i. e.*, the greater the available amount of body fluid, the greater is the diuretic response. In this connection it is important to remember that the presence of edema is no assurance that the patient is not suffering from a lack of *available* salt and water. He may complain of great thirst and present poor turgor of the tissues of the upper half of the body. To overcome the emaciation associated with diuresis in experimental animals used for determining minimal toxic doses of mercurials it has been found that fluid administered by mouth is more effective than that given parenterally.<sup>21</sup>

## SPECIAL PHARMACOLOGY OF THE MERCURIAL DIURETICS

The mode of action or pharmacology of salyrgan remains a matter of debate. The theories may be briefly summed up as follows:

1. The hydrophilic properties of the tissues are diminished.
2. An adrenalin-like action of prolonged duration is produced.
3. An inhibiting effect on the renal tubular epithelium is developed.

The first theory is based on the antidotal effects of supplying fluid to the body and of giving posterior pituitary extract; in other words, it suggests an alteration in water metabolism and postulates an initial blood dilution which is not borne out in fact.<sup>22, 23, 24, 25</sup> Schmitz<sup>24</sup> made determinations of the refractive index of the blood plasma every three minutes after the administration of salyrgan and found no hydremia; on the contrary, the refractive index increased during diuresis indicating hemoconcentration. The early reports of initial blood dilution (increase of hydremia) are now attributed to overemphasis of minor variations and to the time intervals at which determinations were made. Nevertheless, that water metab-

olism is faulty in these cases cannot be denied, since, as already pointed out above, it is well known that a patient may be edematous in the lower extremities and complain of severe thirst and present poor tissue turgor over the upper half of the body. The second theory is based on the interesting studies of Jackson<sup>9</sup> which show that salyrgan is analogous to adrenalin in its action upon the heart, blood vessels, and kidney. The third theory, namely, that the activity of the renal tubular epithelium is depressed, preventing resorption of threshold substances, notably sodium chloride and water is the most generally accepted at the present time. Nonnenbruch,<sup>23</sup> like Schmitz, has shown an initial decrease in hydremia. Chabanier, Lebert, and Lumière<sup>22</sup> have shown an initial drop of blood sodium—in one instance from 5.83 to 2.48 Gm. per liter—and of blood chloride from 6.38 to 3.52 Gm. per liter. For further interesting data in this connection Govaert's studies<sup>26</sup> with transplanted kidneys may be consulted.

Fourneau and Melville<sup>21</sup> in studying toxicity of mercurials made the following important observations. Too rapid injections may cause instant death in a rabbit which would otherwise survive seven to fourteen days. This corresponds precisely with fatality shortly after the administration of the drugs as noted in the earlier part of this paper. Acute intoxication may occur and cause emaciation and death in five days; it is characterized by anuria, diarrhea, and renal and intestinal lesions. Chronic intoxication is associated with some degree of diuresis, terminal diarrhea and renal changes. The authors state that the minimal toxic dose is that weight of the substance expressed in Gm. per kilogram of rabbit which when injected intravenously into animals kept on a *basal water-free diet* leads to *progressive emaciation and death* in seven to fourteen days. This syndrome is distinctly analogous to the one which we describe in human subjects. The mechanism of this chronic intoxication is attributed to *some derangement in water metabolism* (which we would modify to *water and salt depletion*) rather than to an associated nephritis. These authors have made the extremely important observation that when their animals were given water by mouth (200 cc. into the stomach) diuresis would ensue and the animals would recover. They confirmed the observation of H. Gunsberg<sup>27</sup> that water by

mouth is more effective than water administered parenterally. These observations of Fournau and Melville and of Gunsberg form the basis for our method of managing cases of excessive dehydration.

It has been shown that in diuresis due to salyrgan and its allies there is a huge excretion of sodium chloride and water.<sup>20</sup>

It is important to understand that the degree of diuresis is dependent upon the amount of mercurial administered. When the dose of merbaphen is increased from 1 to 2 cc. there is a threefold increase in the excretion of water and sodium chloride and a twofold increase in the duration of the action.<sup>20</sup> The various drugs are available commercially in approximately 10 per cent solutions and it is advisable to begin with a small dose ( $\frac{1}{2}$  to 1 cc.) intramuscularly.

The most popular route for the administration of the mercurials is the intramuscular. Although a number of the drugs may be safely administered intravenously, there is in many instances no distinct advantage to this route. Recently it has been found that rectal administration in the form of suppositories is often effective.

#### CONTRAINDICATIONS TO THE USE OF THE MERCURIAL DIURETICS

In an effort to explain the pathogenesis of the various toxic phenomena of the dehydration syndrome and to determine contraindications, our cases and those reported in the literature have been examined from the standpoint of age, sex, height and weight, type of disease, blood pressure, renal function, degree of diuresis, state of dehydration, urinary changes, blood chemical findings, mode of exitus, postmortem findings, drug employed, and dosage. Sprague and Graybiel<sup>15</sup> found that age, sex, blood pressure, duration of disease, degree of cardiac enlargement, and cardiac rhythm were unimportant in predicting the efficacy of diuresis. Usually the reports of various authors are incomplete and a tabular analysis cannot be made. Nevertheless it is our impression that elderly, atherosclerotic individuals may be less able than others to effect an automatic readjustment of salt and fluid balance after diuresis, particularly if they are thin or cachectic (*i. e.*, with a small available amount of salt and fluid to provide them with a margin of

safety), if already in a poor state of hydration, and if the dosage of the drug has been large.

### THE SYNDROME AND ITS DIFFERENTIAL DIAGNOSIS

The syndrome which we will now discuss in detail occurs with diuresis and is characterized by preliminary restlessness and mental confusion, delirium or even a psychotic state, followed in some instances by apathy, coma, and death. Extreme thirst with exceedingly dry tongue and loss of tissue turgor are often observed. The premonitory restlessness may not appear and apathy may be the first manifestation.

In this connection, it is interesting to observe that severe weakness without other symptoms is often noted after diuresis. This weakness actually represents the first phase of a complete syndrome; it is fairly common and is not dangerous. In patients under long-continued therapy for myocardial insufficiency this symptom is sometimes relieved by interrupting the usual routine for a period of one to two days during which liberal amounts of water and salt are permitted.

Any or all of the symptoms we have noted may occur concomitantly with complications inherent in the underlying disease process or in association with other superimposed complications. However, they are often distinguishable even in the face of these confusing factors and should always be borne in mind when a patient who has been subjected to diuretic therapy appears to be going downhill.

In other words when a waterlogged patient under the influence of diuretics begins to fail one must endeavor to decide whether any of the following conditions are present, and if so whether they are etiologic, contributory or only incidental to the clinical picture:

1. Irremediable myocardial insufficiency.
2. A fresh coronary thrombosis.
3. Exacerbation of acute rheumatic carditis.
4. Pulmonary infarction.
5. Respiratory tract infection.
6. Cerebral vascular accident.
7. True renal insufficiency.
8. Oversedation.

9. Acidotic coma from the use of acidifying salts in cases with impaired renal function.<sup>28</sup>
10. The syndrome herein described.

On close analysis it should be possible to distinguish the true nature of the patient's collapse, if it is borne in mind that he is undergoing diuretic therapy, and that this alone may be the causative factor.

#### MECHANISM OF THE SYNDROME

As has already been implied the syndrome which we describe is dependent on a disturbance in the water and mineral equilibrium of the body. As already stated in the section on pharmacology, Nonnenbruch and Schmitz have shown an initial diminution in hydremia and Chabanier *et al.* have shown an initial drop in blood sodium and chloride. Keith, Barrier and Whelan<sup>29</sup> have found that diuresis, either spontaneous or due to ammonium chloride and novasurol, is associated with an increased excretion of water *and sodium*; there is some loss of other ions but of none so constantly as sodium. This immediately calls to mind the acute collapse of Addison's disease which presents a clinical picture in many ways strikingly similar to the one which we describe—*i. e.*, profound weakness, apathy, coma—and in which the blood sodium is also depleted (Loeb, Atchley, and Stahl<sup>30</sup>) and which may be precipitated by deprivation of sodium. Loeb and his associates have found that the blood sodium (and blood sugar) fall while the blood urea rises and the other chemical and morphologic studies of the blood show evidence of blood concentration.

As pointed out in a previous paper<sup>13</sup> the description of this syndrome is not original with us. In 1898 Eichhorst<sup>14</sup> was able with digitalis and diuretin to produce marked diuresis after which somnolence, disorientation, delirium, and apathy developed in certain cases. Sprague and Graybiel,<sup>15</sup> in 1931, reported a case of malignancy with ascites in which it seemed that death was hastened by the use of salyrgan. A similar observation was made by one of us (Poll) in a patient with a carcinoma of the ovary, carcinomatosis peritonei, and marked ascites. The patient, an elderly woman, was otherwise in good condition. Two cc. of salyrgan were administered intramuscularly. Within twelve hours—after a marked diuresis—the

patient became very restless, quickly lapsed into apathy, followed by coma and death. Srnetz<sup>10</sup> in 1934 stressed the necessity for care in administering salyrgan in severe cardiac insufficiency and mentioned somnolence and mental confusion (phantazieren) following diuresis, but did not mention either the severity of the diuresis or the mechanism of the effects.

### PROPHYLACTIC METHODS AND GENERAL PLAN OF MANAGEMENT

As already indicated, a study of our case reports and those of other observers provides no entirely adequate basis for the prediction and exclusion of patients unfavorable for drastic dehydration therapy. Particular care should be used in the presence of senility, advanced atherosclerosis and cachexia. The renal function as determined by the concentrating power of the kidneys is important.<sup>10</sup> The initial dose should be small since the diuretic response is a function of the dose. If the preliminary dose is ineffective and a large collection of fluid is evacuated from a serous cavity the second dose of the diuretic drug should not be increased since under these circumstances an undesirably large diuretic response is sometimes evoked. It is important to proceed slowly with dehydration and to avoid carrying out too many procedures (such as phlebotomy, thoracentesis, paracentesis abdominis) at one time. This precaution applies particularly in elderly patients with predominating right heart failure.

At times it may be preferable to ignore mild asymptomatic grades of edema rather than to risk producing serious dehydration effects.

### ANTIDOTAL TREATMENT

The foregoing analysis gives the key to therapy in cases in which untoward symptoms have developed. The following measures are employed:

1. Oral administration of water.
2. Oral administration of sodium chloride at first in capsules and later as a 0.1 per cent solution which is effective in the restoration of the sodium content of the blood.<sup>81</sup>
3. Intravenous and subcutaneous administration of salt solutions if the foregoing methods are impossible. If therapy

is delayed the condition may no longer be reversible and may end fatally.

### REPORT OF CASES

The following cases form part of a group previously reported by the authors.<sup>13</sup>

**Case I.**—A sixty-seven-year-old white man entered the hospital with a diagnosis of generalized arteriosclerosis, including cerebral and coronary involvement, and myocardial insufficiency. He had observed exertional precordial pain for ten years and dyspnea and edema for four months. With sedatives and dehydration therapy including the restriction of salt and fluid and 2 intramuscular injections of mercupurin (1 and 2 cc. respectively), the patient lost 30 pounds. Thirteen days after his admission to the hospital and one day after the second injection of mercupurin, it was observed that the patient was suffering from profound weakness. On the following day mental symptoms developed and he became noisy and attempted to strike the nurses. It became necessary to transfer him to another institution.

This case is an instance of weakness and psychosis diagnosed at the time as "psychosis with cardiac disease" following diuresis.

**Case II.**—A sixty-five-year-old man entered the hospital for treatment of myocardial insufficiency due to disease of the coronary arteries. He was placed on dehydration therapy including 1 cc. of salyrgan administered intravenously. Although his original weight was only 94 pounds, he experienced a marked diuresis. The next day he became noisy and had delusions of persecution. It was necessary to administer morphine and chloral. Progressive weakness and obvious dehydration ensued. Despite the fact that fluids were then forced he became stuporous and died with a terminal temperature of 101.4° F.

This case illustrates the point that a patient with a small body weight, *i. e.*, with a small reserve of salt and fluid, should be dehydrated cautiously.

**Case III.**—A sixty-five-year-old woman was admitted to the hospital complaining of dyspnea and edema. The diagnosis was generalized arteriosclerosis, including coronary arteriosclerosis, myocardial insufficiency, right hydrothorax, and peripheral edema. On a dehydration régime including 3 injections of mercupurin, each of 2 cc., she lost 38 pounds in weight over a period of twelve days. At this point, when signs of decompensation had disappeared, and the patient was ready to be out of bed, she became drowsy and uncooperative. When fluids were then forced for a few days the symptoms cleared up, and the patient was able to leave the hospital much improved one month after her admission. Precisely the same sequence of events had been observed on 2 previous admissions to the hospital.

This case is one in which drowsiness and mild mental symptoms regularly followed the period of dehydration.

Case IV.—A sixty-five-year-old man entered the hospital complaining of dyspnea and orthopnea of four months' duration. The diagnosis was generalized arteriosclerosis, coronary arteriosclerosis, auricular fibrillation, chronic bronchitis and emphysema, and myocardial insufficiency. The patient received 3 injections, each of 2 cc., of salyrgan, one day, one week, and two weeks, respectively, after admission to the hospital. During the first two weeks he lost 30 pounds in weight and complained of severe weakness and diarrhea. Four days later stomatitis and pharyngitis developed and there was a slight rise of temperature. The patient became unresponsive and uncooperative, refusing food and fluids. His symptoms were at first ascribed to the use of chloral hydrate. Nevertheless fluids were forced for three days during which time the stomatitis and diarrhea subsided and the patient became more responsive and cooperative. He was permitted to gain several pounds without developing symptoms of congestive failure, and left the hospital one month after admission in good condition.

This is an instance of severe weakness and mild mental symptoms following severe diuresis. The symptoms of diarrhea and stomatitis were probably due to mercurialism although this feature of the case was not investigated. It is important to note that, although the unfavorable symptoms were at first ascribed to the use of sedatives, with the administration of fluids in liberal amounts recovery ensued.

Case V.—A fifty-seven-year-old woman was admitted to the hospital complaining of dyspnea and orthopnea and swelling of the lower extremities. The diagnosis was generalized arteriosclerosis, with coronary involvement, hypertension, and myocardial insufficiency with advanced peripheral edema. On dehydration therapy, including the use of ammonium chloride and neptal, she lost 32 pounds. As the congestive phenomena improved, mental confusion and restlessness appeared. Although there were no focal neurologic signs and no mental symptoms prior to dehydration, the symptoms were ascribed to cerebral arteriosclerosis plus cardiac decompensation. Despite the fact that no further injections of neptal were administered the general dehydration measures were not discontinued. Nevertheless the patient recovered.

After fifteen months the patient returned to the hospital with symptoms of increasing decompensation of five weeks' duration. Over a period of eighteen days, 3 doses of mercupurin were given with marked diuresis. The patient then complained of profound weakness and became uncooperative. On the eighteenth day symptoms of severe vasomotor collapse developed, the clinical picture resembling that of acute coronary thrombosis, though without electrocardiographic changes as compared to previous records. During the next three days fluids were forced and the patient's condition improved remarkably. She was discharged from the hospital after one month.

In this case the periods of dehydration were characterized by restlessness, mental symptoms, profound weakness, and a period of vasomotor collapse. By simply omitting further injections of neptal during her first stay in the hospital and by forcing fluids during her second stay, recovery followed.

## CLINIC OF DR. RUSSELL G. MACROBERT

### LENOX HILL HOSPITAL

---

#### EPILEPSY: BIODYNAMICS AND TREATMENT

**Definition.**—Epilepsy is a disorder of the cerebral neurons characterized clinically by a tendency to recurrent fits. The fits are known now to be disturbances in the continuous electrical activity which maintains consciousness. Epilepsy is to be diagnosed, not upon any characteristic of the fits, which are of great variety, but upon this tendency to periodic recurrence.

**General Conception.**—A tendency to fits once definitely manifested, persists throughout life even from infancy to advanced age, although it may be submerged by medical treatment or improvement in general health. So fixed and constant a physical characteristic seems to justify the assumption of a basis in anatomic structure. But such an assumption is by no means unanimous. There has been no agreement upon any pathognomonic structural imperfection or defect as the basis for the tendency. In 1926<sup>1</sup> I adduced certain evidence to show that the varied pathologic anatomy of epilepsy has a common denominator which satisfactorily explains the fixed tendency. This common denominator is a paucity of functionally active, or impulse-carrying fibers. On the basis of the *developmental* or *acquired* origin of this pathology an etiologic classification can be made of *primary* defect and *secondary* defect epilepsy. As for primary defect epilepsy, the imperfections in development which have been noted in epileptic persons are many and varied, but a paucity of fibers is a consequence which can be ascribed readily to any of them. In secondary defect epilepsy, the functionally active fibers are reduced by changes accompanying destructive lesions, inflammatory, neoplastic, degenerative or traumatic, of the cerebral tissue, its coverings, or its

vascular and spinal fluid channels. Since that time pathologic studies and experimental work on epilepsy (particularly the electrophysiologic studies) have served greatly to increase the plausibility of my hypothesis.

The intermittent disturbances in physiologic function which are the fits have to do first and foremost with the skilled environmental contacts, that is, those processes which maintain consciousness. These physiologic disturbances can be explained in accordance with the specific anatomic fault of defective fiber (conduction) pathways, because consciousness with its expansion and contraction depends upon the transference of impulses among high cerebral units, in particular the receptive centers for sensory stimuli. This intercommunication is maintained electrically and the pathways for these communications are the nerve fibers. Over their network the transference of nerve impulses occurs which permits awareness of self and surroundings and the intellectual functions of attention, memory, deliberation and choice. So, after reviewing briefly the pathologic anatomy, I shall give my hypothesis of the pathologic physiology and illustrate it by describing the probable intracerebral occurrences during a single attack.

**Pathologic Anatomy.**—*Facts Proving It a Cerebral Disease.*—That the epileptic tendency is, first of all, a disorder of the cerebrum seems almost a superfluous statement in view of the fact that the essential feature of the fit is a disturbance of consciousness which is a function of the cerebrum. However, it has been established well by the facts of cerebral disease, electrical experimentation, ablation of certain portions of the brain, experimentation with convulsant drugs, and by a combination of these various methods of investigation, that epilepsy is a disease of the cerebrum and no place else. The same facts have shown the importance of the cortex in the clonic and the subcortical regions in the tonic features of the muscular spasms accompanying convulsions.

*Facts Proving Basis in Anatomic Structure.*—Apart from a life-long constancy of a once established tendency to fits various other facts argue for its basis in imperfect cerebral anatomic structure, such as the following: its close association with mental deficiency and its increased frequency with increased grade of mental deficiency; its greater liability at the

time of incomplete development of the brain in infancy; its common occurrence with destructive cerebral lesions of almost any kind or location; the fixity of the point of onset to a single location for any individual epileptic; the structural cerebral imperfections suggested by the frequent presence of gross bodily anatomic malformations.

*The Common Denominator in Pathologic Anatomy.*—The common denominator in such a varied pathologic anatomy can only be found in structure subserving a function common to all parts or identical in any cerebral location. The *pathways* which carry the intercommunicating impulses, alone fulfil the requirement. A lesion any place which destroys fibers will always produce one identical effect: a difficulty in transmitting the impulses to correlate the various cerebral functional units. That the common denominator of the pathologic anatomy of epilepsy, or the essential epileptic fault, is a paucity of functionally active correlating neurons, thus seems evident.

*Facts Substantiating Common Denominator Hypothesis.*—The close relationship of infancy to epileptic susceptibility is considered due to correlating neurons being incompletely awakened to functional activity by the delayed deposit of the myelin sheath. Three facts in the pathologic anatomy of epilepsy supply supplemental proof of culpability of correlating neurons in this basic instability.

Firstly, lesions chiefly in white matter, such as occur in so-called "demyelinating diseases," seem prone to set up the convulsive tendency. In Schilder's disease, encephalitis, periaxialis diffusa, the expression of which is destruction of myelin sheaths, fits may be the first symptom to draw attention to the patient's illness, but usually appear at some times during the course of the disease. In status dysmyelinatus described by the Vogts, convulsions are part of the clinical picture. King and Meehan<sup>2</sup> in their recent account of Marchiafava's disease, characterized by demyelination of nerve fibers in the corpus callosum, put epileptiform convulsions as the most constant somatic symptom. They quote Bignami and Nazari as obtaining a history of convulsions in 21 of the 22 patients who could give information on this point.

Secondly, the brunt of the disturbance in chronic epilepsy is borne by subcortical structure according to Hodskins and

Yakovlev<sup>3</sup> in their study of the nature and location of the pathology underlying the neurosomatic deterioration of chronic epileptic patients. Peculiar disappearance of fibers in the globus pallidus and corpus striatum, especially a loss of myelin sheaths, was recently demonstrated by Spiller<sup>4</sup> in a case of subcortical epilepsy. As the striate system has no direct cortical communications, but reaches the prefrontal and precentral convolutions by several series of neurons, the tonic convulsions described, and the irritability, loss of temper, tendency to stutter, difficulty in understanding what was read, and impairment of memory, were considered due to loss of function in these correlating neurons.

Thirdly, epileptic attacks occur most frequently in cases of diffuse, slowly infiltrating glioma in which many ganglion cells and nerve cells remain fairly intact between the growing tumor cells, according to List.<sup>5</sup> This type of tumor reduces fibers in number sufficiently to interfere with the facilitation of impulses but does not cause a complete paralysis of function as do the rapidly growing and thoroughly destructive tumors.

*Special Vulnerability of Frontal Lobe.—Autopsies Prove It.*—Autopsies on epileptics indicate the special vulnerability of the frontal lobe to the epileptic tendency, either through its lack of good structural development, or upon its invasion by destructive lesions. Bateman<sup>6</sup> recently reviewed the clinical and pathologic data in a series of 178 brains of persons with convulsions. Only 2 of the brains did not show pathologic change. He concluded that cerebral frontal agenesis was the most predominant and characteristic condition in the brains of patients whose symptoms occurred before the period of pubescence. He divided his material into three groups. One group of 34 included persons of all ages who had active organic disease of the brain. The rest were divided into two groups according to time of onset of convulsions before or after an arbitrary age of puberty as twelve. In the older group of 76 cases the most common pathologic changes were in the cerebrospinal fluid and vascular systems. There were structural developmental defects, but the majority were the result of inflammatory insults to the cerebrospinal circulatory system. In the younger group, whose convulsions occurred before the age of twelve, there were 66 cases and in all these there was

cerebral agenesis which in each instance included the frontal lobes.

*Tumor Statistics Prove It.*—Regarding the location in the cerebrum of tumors most likely to evoke epilepsy, statistics agree on the frontal and are approximately in accord in stating that convulsions occur in about 50 per cent of frontal lobe tumors. In Parker's<sup>7</sup> series, which may be considered representative of other statistics, convulsions occurred in 52 per cent of frontal lobe tumors, in 31.8 per cent of temporal lobe tumors, in 38.3 per cent of corpus callosum tumors, and 30.7 per cent of third ventricle tumors. When the tumor involved a combination of two such important association centers as frontal and temporal, convulsions occurred in every case.

*Pathologic Physiology.—Frontal Lobe Physiology.*—This special vulnerability of the frontal convolutions cannot be ignored in any consideration of the dynamics of epilepsy. But it must be remembered that all parts of the brain are connected with the frontal lobes, and that nervous function is "localized" in all those nervous structures which are thrown into activity in the performance of function. It is doubtful if any nervous activities occur in the cortex exclusively without some participation or reverberation on lower levels. Recent opinion regarding the preponderant physiologic function of the frontal lobe is practically unanimous in ascribing to it synthesis of impulses from all parts of the nervous system which are necessary to form a decision as to action concerning environmental contacts.

Any intrinsic disturbance of the frontal lobes which causes a difficulty in the synthesis of impulses arriving there, leads to a state of indecision and mental confusion. Disturbances in other areas of the brain important for the reception and association of sensory impulses or in pathways relaying such impulses to the frontal lobe, would interfere also with good frontal lobe function and lead to confusion.

*Conception of Epilepsy's Pathologic Physiology.*—My conception of the pathologic physiology of epilepsy includes a state of disturbed frontal lobe function, a mental confusion, as the immediate precursor of the individual attack. The confusion is based upon an inadequate capacity of the frontal lobes to handle a bombardment of cerebral neurons by unusual volleys of afferent stimuli.

*Substantiated by Electrophysiologic Experiments.*—My conception is substantiated by facts derived from recent study and experimentation on the electrical activity of the brain. Confused mental states, associated with imperfect (disturbed) frontal lobe function, produce abnormal fluctuations in electric potential marked by a rhythm of amplitude and frequency approximating in character that occurring during an epileptic attack. Lennox, Gibbs and Gibbs<sup>8</sup> find that the typical disturbance in electrical potential led off from the surface of the skull during petit mal (the outburst of waves of great amplitude and reduced frequency) comes chiefly from the frontal lobes. With such limited capacity for good frontal lobe function as occurs in early infancy, mental deficiency, during sleep in the normal, and other conditions characterized by disturbance of consciousness or extreme mental confusion, such as result from breathing pure nitrogen, overventilating the lungs with room air, and failure of the cerebral blood supply, the amplitude of the waves in the cortical electrogram, is greatly increased, and the frequency is slowed (Gibbs, Davis and Lennox<sup>9</sup>). Davis and Davis<sup>10</sup> showed that babies under six months give large random waves rather than regular rhythms. Regular rhythms of about 4 waves a second begin to appear at about six months. The frequency increases progressively to 7 or 8 waves a second in childhood, and to the adult pattern and frequency by ten or twelve years. Kreezer<sup>11</sup> found that in low-grade mental deficiency large waves of longer duration, and frequency of about 5 waves per second, occurred.

*Intracerebral Occurrences During Epileptic Attack.*—*Fright as an Excitant.*—Gowers stated many years ago that as a direct incitant of the first attack, intense sudden alarm takes the first place. It can be traced in a considerable proportion of cases. In many instances the cause of the alarm seems absurdly inadequate, but that which seems inadequate on first sight may not seem so on further consideration. Gowers also said that the disturbing effect of sudden fear seems the greater when it cannot have its normal consequence, namely, the energetic discharge of the motor centers, to escape from danger.

The chief centers for the control of emotional reactions are located in the diencephalon. Strong emotional excitement invariably results in an immediate discharge of nervous impulses

through the autonomic nervous system. The immediate reactions invoked tend in general to produce functional responses which are beneficial to the individual. For example, there may be a charge of adrenin into the blood stream with consequent changes in the blood flow, or blood sugar may be mobilized for the possibilities of extreme muscular exertion. There may be a marked rise in the number of red blood cells in the blood.

Gibbs, Davis and Lennox tell of two of their patients with grand mal seizures who could be thrown into a seizure by a loud noise. The noise was followed within one-tenth second by a seizure. I have known numerous instances of anxiety and fright being incitants of attacks. J. S., a boy of eleven, whose first attacks were attributed by the family to a period of anxiety and excitement following his being involved with some other children in a petty theft from a local candy store, is one of them. Sudden fright had repeatedly caused later attacks. One afternoon, hearing a knock at the door and expecting his mother, he ran to the door and threw it open. Instead of his mother, he was surprised to find two Catholic nuns. Something in the surprise and in the strange picture of the hooded sisters gave him an excessive fright. He went down almost immediately in a generalized convulsion. It is probable that repetition of frightening situations in dreams may act in the same way. It is probable also that disordered visceral function, hunger, pain, nutritional lack of various kinds, may bombard the cerebrum with excessive afferent stimuli all below conscious levels and act as inciting factors of single attacks. But if we take one generally agreed on, like fright, and trace its probable intracerebral occurrences, a comprehensive view of the biodynamics of epilepsy may be gained.

*Intracerebral Occurrences Following Fright.*—What J. S. saw was carried from his retinae over the optic nerves and tracts to the geniculate bodies and to the occipital cortex. An attempt to associate it with things previously seen, heard and experienced, stored throughout his brain as memories, so as to adjust himself to appropriate present decision or action, a frontal lobe function, apparently failed. A condition of panic and fear evoked primitive defense mechanisms in the diencephalon. Stimulation of the autonomic nervous system followed, and poured into the blood stream the substances sympathin and

acetylcholine, humoral excitants of sympathetic and parasympathetic functions, to prepare him for flight or fight. It is known that each of the billions of red blood cells in the body contains a charge of electricity. The blood cells of a full-grown man have been estimated to contain sufficient electricity to light a 25-watt bulb for five minutes (Biol. Lab., Cold Springs Harbor, L. I.). Autonomic excitation, therefore, increases the electrical charge of the blood stream when it stimulates an immediate production of blood cells. This bodily turmoil bombards the brain, indirectly the frontal lobes, with extra volleys of afferent stimuli. These stimuli mean an increase in the volume of electrical potential being transferred over conduction neurons, a heavier load of electric current which overtaxes the impulse handling or current carrying capacity of fibers. How these volleys of electrical stimuli arrive in force and time to evoke fits must be left for lengthier and more technical descriptions which comprehend the interesting phenomena now being uncovered by the research electrophysiologists relating to the various alterations in spike potential, negative after-potential, and positive after-potential.

**Treatment.**—*Hospitalization.*—The treatment of a patient with convulsions is an individual problem, and if a period of preliminary hospital observation is possible, it is to be recommended. This provides an advantageous opportunity not only to determine the character of the fits but to make an appraisal of much concerning the patient which will help in his future management. A detailed description of the past and present condition is essential and can be obtained at this time. A study of his physiologic functions and a search for organic abnormalities and infectious or other disease processes is only slightly more important than the discovery and correction of bad hygiene in such matters as sleeping, eating and elimination. The more learned regarding the patient's mentality, aptitudes, interests, moods, and also relatives and friends, the more comprehensive the advice which can be given on many points important to favorable progress. It will be possible usually to classify as to primary or secondary defect epilepsy and to diagnose for proper treatment such secondary causes as lues, brain tumor, degenerative diseases and traumatic lesions. The endocrine status can be estimated better with the various diag-

nostic and laboratory aids available in a hospital, and the individual response to various useful medications, the personal preferences or peculiar sensitivity to various foods and any allergic reactions witnessed and recorded.

*Periodic Visits.*—Following the period of hospitalization, regular and frequent observation should be continued over a long period and records and charts of fits and therapeutic measures accurately kept, for in this disorder success in treatment so frequently lies in infinite patience and a persistent attention to detail. The advisability of checking, modifying, and perfecting at regular intervals the important points in daily hygiene and medication cannot be overemphasized. On these routine visits it is well to obtain information regarding all important bodily functions and to reexamine the muscular power, the reflexes, and the cranial nerves, especially the optic disks. A constant vigilance in this regard may disclose, even after long years, a hitherto quiescent brain tumor. So important are the routine visits over a long time that to a certain class of patients, likely to be negligent in making these visits, it may be well to administer a hypodermic injection of iron or some useful remedy, the necessity for which may be comprehended more readily than periodic examination and check-up of therapy.

*General Considerations.*—The range of mentality in epilepsy is from the superior, even gifted, to idiocy. With the lower grades of mentality successful treatment outside an institution is difficult. The best results are with patients having ability and willingness to cooperate. Schooling, occupation, and normal social life are as important for these patients as for any other person and should be strived for. The patient should not be permitted to regard himself as an abnormal person. Success in treatment is so possible in most cases that the epileptic is entitled from the start to a greater degree of optimism and hopefulness than unfortunately usually is vouchsafed him. Too frequently these points are neglected, and pessimism, inferiority and despondency arise which have to be treated in addition to the epileptic disturbance. Children are removed from school, deprived of normal companionship, ordinary pleasures and exercise, when such a simple measure as a small dose of phenobarbital at bedtime might be almost all that is necessary to control their tendency to fits.

Advice as to marriage and parenthood for these patients frequently is requested. There may be no reason why a patient whose attacks are under control should be denied marriage. Neither is there reason for parenthood to be denied, providing the tendency to fits was caused by a secondary defect of the nervous system, of toxic, inflammatory, or traumatic causation. No hereditary influence need be expected in such cases any more than a man who has lost a leg through injury need be expected to procreate a one-legged infant. Early statistics on the heredity of epilepsy were based chiefly on mentally defective institutional cases, mostly developmental defect epilepsy, and gave rise to a false picture of heritability. This is not warranted because the epileptic tendency from acquired defect causes is also prevalent among mentally competent and excellent citizens.

Besides the differentiation of primary defect and secondary defect epilepsy so that special treatment of secondary causes and defects responsible for the tendency can be instituted when possible, it is important to remember that the individual seizure is a disturbance in electrical conductivity among the cerebral neurons. Conditions and drugs which influence electric conductivity of cerebral neurons are of importance and have been studied. From the recordings of electro-encephalograms it is known that phenobarbital and sodium bromide prevent or alter the pathologic electrical activity associated with the seizure and these two drugs are the ones which for a long time have proved most successful in the treatment of epilepsy.

The bombardment of the cerebral neurons with excessive and unabsorbable afferent stimuli, which is in actuality an overloading with electric potential must not be forgotten, for it permits another influence to be exercised upon the disorder by treatment. These excessive stimuli may arise from disordered or diseased viscera, or from disturbed physiology due to improper care of the body. While sugar, oxygen, and lactic acid are said to be the only foods of the brain, improper nutrition of the body from a poorly balanced diet, inadequate mineral salts or vitamins, can be registered by electrical stimuli in the brain. Such a variety of disturbing afferent stimuli as may be set up by inadequate secretion of important endocrine glands, intrapsychic tension, mental conflict, fear and worry also must be taken into consideration.

The treatment of secondary defect epilepsy constitutes, in a word, consideration of two conditions, the tendency to fits and the causative factor. The appropriate treatment of the organic cerebral consequences of such secondary factors as tumor, lues, trauma, toxins, often may be quite obvious, but at other times will constitute an occasion for the use of experienced and conservative good judgment and the rarest skill. This statement applies particularly to various surgical measures for the alleviation of scar tissue, pachionian adhesions, and old traumatic lesions. We have witnessed a vogue for encephalography in epilepsy during the last few years. This painful procedure will frequently disclose air spaces over atrophic cerebral tissue, and enlarged ventricles. If the procedure be restricted to those cases in which a lesion, calling for operative interference, such as tumor, is suspected, and is not done routinely to expose situations for which surgical intervention is of no avail or contraindicated, it has its place. If the pathologic anatomy of epilepsy is appreciated properly, many abnormalities can be assumed without the patient being subjected to an encephalography, which in no way will alter the treatment of the case.

*The Average Case.*—For the average patient the amount of phenobarbital required may range from  $\frac{3}{4}$  to 3 grains daily. It is well to start with the smaller dose and increase it to the point necessary to control the seizures, when the patient has been put in the best possible environmental, physiologic, emotional and mental condition. A great many patients can be maintained free from attacks by comparatively simple treatment and routine supervision.

*The Difficult Case.*—The difficult cases are those with some situation or condition which cannot be adjusted easily, or whose cooperation is inadequate. Many of these difficult cases are burdened with numerous petit mal disturbances. Sometimes much larger doses of phenobarbital, gradually arrived at, or combinations of sodium bromide and phenobarbital will meet the problem. In others, mephobarbital, pentobarbital sodium and certain drugs acting upon the sympathetic and parasympathetic systems, as seem indicated by the condition of these systems, are of great assistance and may be used as accessories. Atropine, benzedrine sulfate, ergotamine tartrate, prostigmin, may be tried under close supervision.

Advice as to marriage and parenthood for these patients frequently is requested. There may be no reason why a patient whose attacks are under control should be denied marriage. Neither is there reason for parenthood to be denied, providing the tendency to fits was caused by a secondary defect of the nervous system, of toxic, inflammatory, or traumatic causation. No hereditary influence need be expected in such cases any more than a man who has lost a leg through injury need be expected to procreate a one-legged infant. Atropine, benzedrine sulfate, ergotamine tartrate, prostigmin, may be tried under close supervision.

Regarding diet, much has been written, and certain ones extolled. My policy is to seek for a normal, well-balanced diet, suitable to the age, desirable weight and energy requirements of the patient. I especially wish to be assured of adequate protein. I find no benefit in inflicting the hardship of fluid deprivation, and make no restrictions of fluid intake except where there is evidence of inadequate output. In a word, the treatment of the epileptic is the humane consideration of the happiness, welfare, and general good health of a person whose brain is subject to occasional functional electrical disturbances requiring continuously, in some amount, some special medication such as phenobarbital or sodium bromide. *When* the patient is to be explored surgically is a matter for the judgment of a good neurologist convinced of the success of conservative medical treatment for almost all epileptic patients.

## INDEX TO VOLUME 21

- ABDOMEN, acute, general practitioner and, *July*, 1095  
 Abdominal angina, *Jan.*, 239  
   enlargements in children, diagnosis, *May*, 813  
   pain, low-grade, in children, diagnosis of causes, *Sept.*, 1373  
 Abscess, bone (Brodie), simulating arthritis, *Nov.*, 1763  
   peritonsillar, sulfanilamide in, *Sept.*, 1451  
 Acacia in nephrotic edema, *Nov.*, 1842  
 Acanthosis nigricans, *May*, 863  
 Acid intoxication in diabetes, management, *Jan.*, 16  
   regurgitation, dyspepsia and, *May*, 648  
   therapy, antiseptic, in urinary tract infections, *March*, 606  
 Acidosis from sulfanilamide, *Sept.*, 1459  
 Addison's disease, skin manifestations, *May*, 862  
 Adenitis, sulfanilamide in, *Sept.*, 1451  
 Adenomatous enlargement of prostate, *Sept.*, 1440  
   goiter without hyperthyroidism in children, *May*, 834  
 Adolescent goiter, *May*, 832  
 Adrenals, obesity and, *Jan.*, 28  
 Agglutination reactions in arthritis, *Nov.*, 1665, 1668  
   test in tularemia, *May*, 858  
 Agranulocytic angina in childhood, *Jan.*, 105  
 Ainhum, *Jan.*, 252  
 Aleukemia, *March*, 357  
 Aleukemic leukemia in childhood, *Jan.*, 107  
   appendicitis and, differentiation, *Jan.*, 108  
   myelogenous leukemia, *March*, 353  
   myelosis, *March*, 354  
 Alkalosis, dyspepsia and, *May*, 669  
 Allergic factor in migraine, *Jan.*, 123, 159  
   manifestations, internal medicine and, interdependence, *Sept.*, 1565  
 Allergy as factor in arthritis, *Nov.*, 1670  
 Allergy, dyspepsia and, *May*, 670  
   food, *Jan.*, 119  
   studies in, *March*, 613  
 Amebiasis, treatment, *May*, 717  
 Amebic dysentery, *Jan.*, 159  
 Amyloid deposits in skin, *May*, 869  
 Amyloidosis, systematized, *May*, 869  
 Amyotonia congenita as cause of malnutrition in infancy, *Sept.*, 1276  
 Anemia, aplastic, in childhood, *Jan.*, 106  
   erythroblastic, *Jan.*, 97  
   from vitamin C deficiency, *May*, 746  
   hemolytic, acute, from sulfanilamide, *Sept.*, 1459  
   congenital, in infancy and childhood, *March*, 401  
   of pregnancy, *Nov.*, 1865  
   diagnosis, *July*, 1185  
   treatment, *July*, 1185  
   pernicious, *March*, 333. See also *Pernicious anemia*.  
 Anemic ulcers of leg, treatment, *Jan.*, 244  
 Angina, abdominal, *Jan.*, 239  
   agranulocytic, in childhood, *Jan.*, 105  
   pectoris, hypertension and, *July*, 1054  
 Ankle, tuberculosis of, *Nov.*, 1728  
 Ankylosis in arthritis, surgery for, *Nov.*, 1635  
 Anorexia, dyspepsia and, *May*, 649  
 Antepartum bleeding, *Nov.*, 1866  
   fetal death, diagnosis and management, *Jan.*, 300  
 Antifibrinolysin test in arthritis, *Nov.*, 1666  
 Antiseptic acid therapy in urinary tract infections, *March*, 606  
 Antistreptolysin test in arthritis, *Nov.*, 1666, 1669  
 Aorta, coarctation of, in children, diagnosis, *Sept.*, 1293  
 Aortitis, syphilitic, diagnosis of, *July*, 1013  
   pathologic physiology, *July*, 1015  
   treatment of, *July*, 1013, 1026  
   uncomplicated, prevention of, *July*, 1023

- Aphonia, hysterical, diagnosis of, *July*, 1211  
 malingering in, *July*, 1211  
 treatment of, *July*, 1211
- Apical systolic murmur in rheumatic heart disease, *Sept.*, 1303, 1307
- Aplastic anemia in childhood, *Jan.*, 106
- Appendicitis, aleukemic leukemia in childhood and, differentiation, *Jan.*, 108  
 dyspepsia and, *May*, 660
- Appendix, roentgen study, in arthritis, *Nov.*, 1657
- Arms, paroxysmal attacks of pain in, heart disease and, *July*, 1009
- Arrhythmias, cardiac neurosis and, *March*, 454  
 sinus, *July*, 1033
- Arsenicals in urinary tract infections, *March*, 611
- Arteries, cerebral, thrombosis of, *Sept.*, 1523
- Arthritic cripple, surgical reconstruction of, *Nov.*, 1623
- Arthritis, acute suppurative, recognition and treatment, *Nov.*, 1751  
 atrophic, *Nov.*, 1598, 1623, 1649, 1663  
 chronic, bee venom in, *Nov.*, 1617  
 bilirubin and bile salts intravenously, *Nov.*, 1619  
 bone abscesses (Brodie) simulating, *Nov.*, 1763  
 colonic irrigations in, *Nov.*, 1613  
 controlled rest and exercise in, *Nov.*, 1606  
 diathermy in, *Nov.*, 1822  
 diet in, *Nov.*, 1609  
 drug therapy, *Nov.*, 1610  
 electrotherapy in, *Nov.*, 1819  
 etiology, roentgen difficulties in determining, *Nov.*, 1649  
 urologic factor, *Nov.*, 1699  
 fever therapy, *Nov.*, 1821  
 foci of infection in, *Nov.*, 1671, 1675, 1685, 1689, 1699, 1705  
 removal, *Nov.*, 1606  
 roentgen study, *Nov.*, 1653  
 gallbladder infection as factor, *Nov.*, 1705  
 gold therapy, *Nov.*, 1615  
 heliotherapy in, *Nov.*, 1822  
 hydrotherapy in, *Nov.*, 1827  
 low back pain due to, *Nov.*, 1776  
 management of, in home, *March*, 511-524  
 massage and exercises in, *Nov.*, 1809, 1812
- Arthritis, chronic, oral foci of infection *Nov.*, 1607  
 painful foot of, *Nov.*, 1785  
 causes, *Nov.*, 1786  
 treatment, *Nov.*, 1790  
 operative, *Nov.*, 1793  
 physiotherapy in, *Nov.*, 1809  
 psoriasis in, *Nov.*, 1807  
 relief of mental depression, *Nov.*, 1605  
 roentgen therapy, *Nov.*, 1618  
 seminal tract infection in, *Nov.*, 1700  
 sinuses as foci of infection, *Nov.*, 1607, 1654, 1683  
 streptococcus in, immunologic tests for, *Nov.*, 1665, 1668  
 evidence for, *Nov.*, 1667  
 rôle of, *Nov.*, 1663  
 sulfur therapy, *Nov.*, 1616  
 surgery in, *Nov.*, 1623  
 teeth as foci of infection, *Nov.*, 1653, 1671  
 tonsils as foci of infection, *Nov.*, 1607, 1675  
 treatment, *Nov.*, 1602  
 urologic factor, *Nov.*, 1699  
 vaccine therapy, *Nov.*, 1611  
 vitamin therapy, *Nov.*, 1618  
 x-ray study and treatment, *Nov.*, 1641  
 classification, *Nov.*, 1596, 1641  
 roentgenologic difficulties, *Nov.*, 1641  
 degenerative, *Nov.*, 1600  
 female pelvis as focus, *Nov.*, 1689  
 foci of infection, cultures from, *Nov.*, 1667  
 gonorrheal, *Nov.*, 1691, 1694, 1825  
 treatment by physically induced fever, *Nov.*, 1709  
 hypertrophic, *Nov.*, 1600, 1649, 1663  
 in *Brucella melitensis* infections, *Nov.*, 1747  
 in leukemia in childhood, *Jan.*, 101  
 mixed type, *Nov.*, 1600  
 of scarlet fever, *Nov.*, 1741  
 pneumococcal, *Nov.*, 1739  
 problem of, *Nov.*, 1595  
 rheumatoid, *Nov.*, 1598, 1649, 1663, 1667, 1807, 1813, 1825  
 fibrositis and, differentiation, *Nov.*, 1802  
 surgery in, *Nov.*, 1623  
 suppurative, in scarlet fever, *Nov.*, 1744  
 symposium on, *Nov.*, 1593  
 tuberculous, *Nov.*, 1723

- Arthritis, tuberculous, laboratory aids in diagnosis, *Nov.*, 1731  
rheumatic, *Nov.*, 1601  
treatment, *Nov.*, 1732
- Arthrodesis in arthritis, *Nov.*, 1634
- Arthropathia psoriatica, *Nov.*, 1807
- Arthroplasty in arthritis, *Nov.*, 1635
- Artificial pneumothorax, contraindications, *July*, 1200  
danger signals, *July*, 1206  
indications for and technic of, *July*, 1193  
for terminating, *July*, 1208  
management, *July*, 1207  
pathologic considerations, *July*, 1197  
physiologic considerations, *July*, 1194  
use of apparatus, *July*, 1204
- Ascites with heart murmur, *July*, 1008
- Asthenia, neurocirculatory, *March*, 471  
cardiac neurosis and, *March*, 451, 453
- Asthma and hay fever, etiologic relationship and clinical importance, *July*, 1125  
cardiac hypertension and, *July*, 1052  
food allergy and, *Jan.*, 121, 125  
pollen, *Jan.*, 137
- Athyreotic cretinism, *May*, 843
- Auricular fibrillation, *July*, 1041  
flutter, *July*, 1040
- Avitaminosis, obesity and, differentiation, *Jan.*, 24
- BACILLUS coli infections, sulfanilamide in, *Sept.*, 1453  
tubercle, infection of prostate with, *Sept.*, 1434  
welchii infections, sulfanilamide in, *Sept.*, 1453
- Back, low, disability of, diagnosis and treatment, *May*, 893  
lower, pain in, conditions causing, differential diagnosis, *Nov.*, 1771
- Bacterial endocarditis in children, diagnosis, *Sept.*, 1308  
subacute, *July*, 1011
- Basedow's disease in children, *May*, 835
- Pechterew's disease, *Nov.*, 1755
- Bees venom in arthritis, *Nov.*, 1617
- Behavior and personality of children, effect of head injury on, *Sept.*, 1335-1365  
etiology, *Sept.*, 1347  
prognosis, *Sept.*, 1351  
treatment, *Sept.*, 1352
- Belching, dyspepsia and, *May*, 648
- Bemax, *July*, 1237
- Beriberi from vitamin B<sub>1</sub> deficiency, *May*, 742
- Beta hemolytic streptococcus infections, sulfanilamide in, *Sept.*, 1450
- Betabion, *July*, 1238
- Betaxin, *July*, 1238
- Bilirubin and bile salts intravenously in arthritis, *Nov.*, 1619
- Birth palsies, progressive, *Sept.*, 1387
- Blindness, night, from vitamin A deficiency, *May*, 739
- Blood pressure, normal, *Jan.*, 220  
sedimentation test in clinical medicine, *Sept.*, 1537  
in disease, variations in, *Sept.*, 1544  
methods for determining, *Sept.*, 1538  
tissue culture of, in leukemia in childhood, *Jan.*, 115  
transfusion in nephrotic edema, *Nov.*, 1842  
in pneumonia in children, *Jan.*, 203
- Bone abscesses, chronic (Brodie), simulating arthritis, *Nov.*, 1763  
infection, roentgen study, in arthritis, *Nov.*, 1658  
rider's, *Jan.*, 269
- Bones, diseases of, blood sedimentation rate in, *Sept.*, 1547
- Brain in essential hypertension, *Jan.*, 225
- Bright's disease. See *Nephritis*.
- Broadbent's sign, *July*, 975
- Brodie's abscess simulating arthritis, *Nov.*, 1763
- Bronchocele in children, *May*, 832
- Bronze diabetes, *May*, 863
- Brucella melitensis infections, arthritis in, *Nov.*, 1747
- Buerger's disease, *Jan.*, 245
- Burns, x-ray, ulcers of leg from, *Jan.*, 253
- CACHEXIA strumipriva, *May*, 847
- Calcinosis, *May*, 868
- Calculus, prostatic, *Sept.*, 1436
- Capsular contraction in arthritis, surgery in, *Nov.*, 1631, 1633
- Carbohydrates in pregnancy, *March*, 550
- Carcinoma of prostate, *Sept.*, 1445
- Cardiac diagnosis, missed, *July*, 1003  
edema, in nephritis, *Nov.*, 1843  
infarction, blood sedimentation rate in, *Sept.*, 1547

- Cardiac insufficiency, early recognition, in presence of pregnancy, *July*, 1059
- neurosis, arrhythmias and, *March*, 454
- coronary thrombosis and, *March*, 459
- heart murmurs and, *March*, 462
- hypertension and, *March*, 458
- misinterpretation of symptoms and signs, *March*, 461
- neurocirculatory asthenia and, *March*, 451, 453
- organic heart disease and, *March*, 457
- paroxysmal tachycardia and, *March*, 456
- recognition, *March*, 449
- rheumatic valvular heart disease and, *March*, 457
- treatment, *March*, 440
- pain, drugs in, *July*, 1080
- psychoneuroses, *March*, 450
- rates, and rhythms, abnormal, diagnosis and treatment, *July*, 1033
- rhythms and rates, drugs in, *July*, 1081
- Cardiovascular diseases, diagnosis of, simplicity in, *July*, 959
- drugs in, *July*, 1073
- syphilitic, serologic tests in, *July*, 1021
- treatment of, *July*, 1023
- phenomena of vitamin B deficiency, *July*, 1231
- system, changes in, from vitamin B<sub>1</sub> deficiency, *May*, 743
- Cardiovascular-renal disease, *Jan.*, 219
- Caries, dental, from vitamin C deficiency, *May*, 746
- from vitamin D deficiency, *May*, 750
- Casein preparations in nephrotic edema, *Nov.*, 1838
- Catarrhal colitis, *Sept.*, 1470
- jaundice, *Sept.*, 1507
- Cathartics in chronic myocardial failure, *July*, 1079
- Celiac disease, *Jan.*, 149
- Central nervous lesion, obesity and, *Jan.*, 29
- Cerebral arteries, thrombosis of, *Sept.*, 1523
- birth palsies, *Sept.*, 1387
- developmental defects, congenital, as cause of malnutrition in infancy, *Sept.*, 1277
- Cervix uteri as focus in arthritis, *Nov.*, 1689
- Chemical nephrosis, acute, treatment, *May*, 778
- Chest pain, noncardiac cause, *March*, 461
- Child, nervous, practitioner's responsibility toward, *March*, 525
- Children, undernutrition in, *July*, 1167
- Chlorosis, *March*, 389
- Cholecystic disease, dyspepsia and, *May*, 658
- Cinchophen in arthritis, *Nov.*, 1610
- Circulation, failure of, congestive and noncongestive clinical features, *March*, 481
- Cirrhosis of liver, *Sept.*, 1509
- Clawtoes in arthritis, *Nov.*, 1791
- Coarctation of aorta in children, diagnosis, *Sept.*, 1293
- Colitis, catarrhal, *Sept.*, 1470
- gravis, *Sept.*, 1472
- mucous, *Sept.*, 1465
- spastic, *May*, 721
- treatment, *May*, 731
- suppurative, *Sept.*, 1472
- ulcerative, *Sept.*, 1470
- idiopathic, *Sept.*, 1472
- treatment, *May*, 715
- Collapse, *March*, 489
- causes, *March*, 494
- combined occurrence of congestive heart failure with, *March*, 498
- treatment, *March*, 499-508
- Colloid goiter, diffuse, in children, *May*, 832
- Colon, diseases of, dyspepsia and, *May*, 662
- functional disorders, *May*, 721
- allergy to food and, *May*, 728
- environment and, *May*, 726
- etiology, *May*, 724
- fear of disease and, *May*, 727
- heredity and, *May*, 729
- irregular habits and, *May*, 729
- laxatives and, *May*, 728
- physical signs, *May*, 721
- symptoms, *May*, 721
- treatment, *May*, 731
- irritable, *July*, 1107
- case histories, *July*, 1116-1124
- diagnosis of, *July*, 1109
- etiology of, *July*, 1108
- treatment of, *July*, 1113
- medical affections, *Sept.*, 1461
- Colonic irrigations in arthritis, *Nov.*, 1613
- neuroses, *July*, 1107
- Colsulanyde, *Sept.*, 1449
- Coma, diabetic, prevention of, *Jan.*, 11
- Complement fixation reactions in arthritis, *Nov.*, 1665, 1669

- Congenital anomalies as cause of malnutrition in infancy, *Sept.*, 1275  
 cerebral developmental defects as cause of malnutrition in infancy, *Sept.*, 1277  
 enlargement of verumontanum, *Sept.*, 1428  
 goiter, *May*, 831  
 heart disease as cause of malnutrition in infancy, *Sept.*, 1277  
   in children, diagnosis, *Sept.*, 1291  
 hemolytic anemia in infancy and childhood, *March*, 401  
 hypertrophy of thyroid gland, *May*, 831  
 myxedema, *May*, 847  
 obstruction at vesical neck, *Sept.*, 1424  
   valves of prostate, *Sept.*, 1425  
 Congestive myocardial failure, cathartics in, *July*, 1079  
   digitalis in, *July*, 1073  
   diuretics in, *July*, 1077  
   morphine in, *July*, 1079  
   salts in, *July*, 1079  
 Conjunctival test for pollinosis, *Jan.*, 132  
 Consciousness, temporary loss, heart disease and, *July*, 1010  
 Constipation, *May*, 691  
   diagnosis, *May*, 696  
   dyspepsia and, *May*, 664  
   in disease, treatment, *May*, 705  
   simple, *Sept.*, 1461  
   symptoms, *May*, 694  
   treatment, *May*, 697  
 Convulsions, heart disease and, *July*, 1010  
 Coronary occlusion, acute, diagnosis of, *July*, 991  
   treatment of, *July*, 997  
   hypertension and, *July*, 1055  
   thrombosis, cardiac neurosis and, *March*, 459  
 Corrigan pulse, *July*, 974  
 Cowgill formula, *July*, 1232  
 Cretinism, *May*, 843  
   athyreotic, *May*, 843  
 Cryptorchism, gonadotropic treatment, *Jan.*, 207, 212, 213  
 Cutaneous lesions from vitamin A deficiency, *May*, 739  
   manifestations of systemic disease, *May*, 861  
   test for pollinosis, *Jan.*, 129  
 Cyanosis from sulfanilamide, *Sept.*, 1458  
 Cysts, obstructive, at vesical orifice, *Sept.*, 1428  
   of prostate, *Sept.*, 1427  
 DEFENSIVE neuroses, recognition and management, *Jan.*, 271  
 Deficiency diseases, dyspepsia and, *May*, 670  
   treatment, *May*, 719  
 Dehydration treatment in heart disease, dangers, *Nov.*, 1873  
 Dental caries from vitamin C deficiency, *May*, 746  
   from vitamin D deficiency, *May*, 750  
 Dermatitis, food allergy and, *Jan.*, 126  
 Dermatology, commonly missed diagnoses in, *March*, 621  
 Dermatomyositis, *Jan.*, 267  
 Dextrocardia in children, diagnosis, *Sept.*, 1292  
 Diabetes, acid intoxication in, management, *Jan.*, 16  
   bronze, *May*, 863  
   early stages, care in, *Jan.*, 15  
   emergency program in, *Jan.*, 15  
   ferric chloride test in, *Jan.*, 14  
   mellitus in pregnancy, *Nov.*, 1862  
   precomatose case, first period management, *Jan.*, 18  
   protamine insulin in, *March*, 417  
   renal threshold in, *March*, 431  
   trauma in relation to, *March*, 441  
   treatment, in presence of high threshold, *March*, 432  
   of low renal threshold, *March*, 436  
 Diabetic coma, prevention, *Jan.*, 11  
 Diagnosis, pediatric, common errors in, *March*, 535  
 Diarrhea, examination of stools and rectal discharges, *May*, 711  
   physical examination in, *May*, 710  
   proctoscopic examination, *May*, 712  
   roentgenologic examination, *May*, 713  
   symptoms, *May*, 709  
   treatment, *May*, 707  
 Diarrheal diseases as cause of malnutrition in infancy, *Sept.*, 1282  
 Diathermy in arthritis, *Nov.*, 1822  
   treatment of chronic gonorrhea in women, *July*, 1226  
 Diathesis, hemorrhagic, from vitamin C deficiency, *May*, 746  
 Diet, daily, during pregnancy and lactation, *March*, 560  
   during pregnancy and nursing period, *March*, 547  
   in arthritis, *Nov.*, 1609  
   in chronic arthritis, *March*, 520  
   in heart disease, *July*, 1085  
   in nephrotic edema, *Nov.*, 1836

- Cardiac insufficiency, early recognition, in presence of pregnancy, *July*, 1059
- neurosis, arrhythmias and, *March*, 454
- coronary thrombosis and, *March*, 459
- heart murmurs and, *March*, 462
- hypertension and, *March*, 458
- misinterpretation of symptoms and signs, *March*, 461
- neurocirculatory asthenia and, *March*, 451, 453
- organic heart disease and, *March*, 457
- paroxysmal tachycardia and, *March*, 456
- recognition, *March*, 449
- rheumatic valvular heart disease and, *March*, 457
- treatment, *March*, 440
- pain, drugs in, *July*, 1080
- psychoneuroses, *March*, 450
- rates, and rhythms, abnormal, diagnosis and treatment, *July*, 1033
- rhythms and rates, drugs in, *July*, 1081
- Cardiovascular diseases, diagnosis of, simplicity in, *July*, 959
- drugs in, *July*, 1073
- syphilitic, serologic tests in, *July*, 1021
- treatment of, *July*, 1023
- phenomena of vitamin B deficiency, *July*, 1231
- system, changes in, from vitamin B<sub>1</sub> deficiency, *May*, 743
- Cardiovascular-renal disease, *Jan.*, 219
- Caries, dental, from vitamin C deficiency, *May*, 746
- from vitamin D deficiency, *May*, 750
- Casein preparations in nephrotic edema, *Nov.*, 1838
- Catarrhal colitis, *Sept.*, 1470
- jaundice, *Sept.*, 1507
- Cathartics in chronic myocardial failure, *July*, 1079
- Celiac disease, *Jan.*, 149
- Central nervous lesion, obesity and, *Jan.*, 29
- Cerebral arteries, thrombosis of, *Sept.*, 1523
- birth palsies, *Sept.*, 1387
- developmental defects, congenital, as cause of malnutrition in infancy, *Sept.*, 1277
- Cervix uteri as focus in arthritis, *Nov.*, 1689
- Chemical nephrosis, acute, treatment, *May*, 778
- Chest pain, noncardiac cause, *March*, 461
- Child, nervous, practitioner's responsibility toward, *March*, 525
- Children, undernutrition in, *July*, 1167
- Chlorosis, *March*, 389
- Cholecystic disease, dyspepsia and, *May*, 658
- Cinchophen in arthritis, *Nov.*, 1610
- Circulation, failure of, congestive and noncongestive clinical features, *March*, 481
- Cirrhosis of liver, *Sept.*, 1509

pain is very severe and is associated with hematemesis or melena, should suggest the possibility of a penetrating type of lesion. Occasionally, a patient who has a duodenal ulcer will complain only of pain in the back, which has the usual characteristics of epigastric pain.

The pain in the thorax, which is most frequently diagnostic of a perforating peptic ulcer, originates in a well defined epigastric region, spreads from there upward along either margin of the sternum, and then extends into the depths of the thorax. This pain is usually lancinating and of short duration. At times, the pain seems to originate in a region buried deeply beneath the middle portion of the sternum. This type of pain occurs most frequently in the presence of perforating gastric lesions which are situated high in the stomach, but it may be present when only a duodenal ulcer is demonstrable at laparotomy. The pain in the thorax is almost always associated with pain in the epigastrium or with pain in the upper right abdominal quadrant, which comes on late following meals and has the characteristic sequence of the pain of ulcer. The severe epigastric pain which is referred to the thorax is not always relieved by the taking of food or alkali.

The pain caused by peptic ulcer usually occurs several hours after meals. If only a small amount of food is eaten, the pain usually comes on more quickly than it does after full meals.

Patients who have peptic ulcer often have distress which wakes them at night, but this is more noticeable among those who have duodenal or gastrojejunal ulcer than it is among those who have gastric ulcer. The manner in which pain of peptic ulcer is controlled is characteristic. Almost invariably, if the ulcer is uncomplicated, the pain will disappear promptly after the ingestion of food or of alkali, or often after the ingestion of even a glass of water. Change of posture, rest, sedatives, vomiting, or gastric lavage will also stop the pain promptly. The pain caused by penetrating ulcer or by acute indurated or obstructing ulcer is less consistently relieved by taking food or alkali.

Recently, we have been impressed by the beneficial effects on the pain and on the syndrome of ulcer in general, which follow the use of drugs which tend to cause relaxation. Large doses of belladonna, bromides, and barbiturates seem to control the pain of ulcer rapidly.

Nausea and vomiting are not uncommon in cases of duodenal ulcer. The nausea may arise while the pain is present or it may develop several hours after a meal and may be independent of pain. At times, the nausea is associated with regurgitation of small amounts of sour material. Taking some alkali, drinking milk, or eating a small amount of food may bring relief.

When vomiting ensues, as a rule, the nausea, as well as the eructation of acid material, stops, as does also the pain, which not infrequently accompanies these other symptoms. Vomiting frequently occurs at the time when the pain has reached its maximal intensity. The vomitus usually consists of a sour fluid which contains variable amounts of food. Occasionally, streaks of blood are noticeable.

A certain rhythmicity is maintained in the appearance and disappearance of the symptoms of acid eructation, flatulence, and vomiting. In some cases exactly similar experiences are repeated from day to day. Some patients perhaps become accustomed to the daily repetition of identical difficulties and, therefore, do not seek medical advice or treatment for a long time. When the syndrome loses this rhythmicity, it usually signifies that some complication is arising, that some obstruction to the normal gastric outlet is developing, or that deeper penetration of the wall of the viscus is beginning to take place.

*Gastrojejunal Ulcer.*—The general characteristics of the syndrome caused by gastrojejunal ulcer are similar to those caused by the original lesion. There is a tendency, however, for the symptoms of gastrojejunal ulcer to be more severe than those of the initial lesion. Periodicity is not so consistently a part of the syndrome as it is in cases of primary ulceration. The periods of relief are usually brief and often the relief is incomplete. Distress usually appears an appreciable length of time following a meal. It frequently comes on earlier, however, than it does in cases of duodenal ulcer. At times, pain occurs immediately following the ingestion of food, and then, after a few minutes, disappears, to reappear an hour or so later. Alkalies are more or less efficacious in the treatment of this type of ulcer. It is frequently noted, however, that the symptoms are not so promptly or so completely relieved in this way as were the symptoms of the original lesion.

The situation of the pain of gastrojejunal ulcer is usually characteristic. The patient will call attention to the fact that his pain is not in the region of the original pain, but is further to the left and lower than it used to be. The pain may originate in the region of preoperative pain and then may be referred downward. This is as characteristic as though the pain actually originated in the lower part of the abdomen.

The pain of jejunal ulcer, particularly if the ulcer is of the perforating type, frequently is referred to the back in a region definitely lower than the usual Boas' point, which is the characteristic site of the referred pain of primary ulcers. Nausea and flatulence, which occur at the time of the pain, are not unusual symptoms. These symptoms are frequently relieved by rest, or by the taking of food or an alkali.

Hemorrhage is not a rare complication of gastrojejunal ulcer. In 24 per cent of cases of gastrojejunal ulcer the history reveals that the patients have vomited blood or have passed tarry stools. The bleeding in these cases is usually intestinal and is more likely to be an oozing than a massive hemorrhage.

Careful questioning of patients who present themselves with a well established syndrome of gastrojejunal ulcer usually discloses the fact that prior to the development of definite symptoms there were periods of uncomfortable distention and complete absence of any desire to eat. Nausea is intense and the patient occasionally vomits large amounts of gastric residue. Unless such a patient happens to be seen during one of these brief attacks, nothing abnormal is demonstrable.

These periodic episodes of retention frequently antedate the recurrence of a consistent painful syndrome by many months. Spasm about the stoma, which is the result of early recurring ulcer or gastrojejunitis, is probably the cause of such episodes of temporary retention.

*Duodenal Stasis and Obstructing Lesions of the Upper Portion of the Small Intestine.*—It is generally assumed that it is extremely rare for pathologic processes to invade the upper portion of the jejunum or that portion of the duodenum distal to the site of an ulcer. There has developed, therefore, a false sense of security in assuming that the small intestine need not be seriously considered in most differential diagnostic considerations. The small intestine, almost in its entirety, remains

a relatively unexplored domain, and our knowledge regarding this portion of the intestinal tract seems lamentably inadequate. No doubt, thorough investigation of this region occasionally would furnish an explanation for some of the syndromes now catalogued under the diagnosis of "gastro-intestinal neurosis."

As an entity of clinical and pathologic significance, duodenal stasis has been discussed for many years. Unfortunately, certain physicians have been too ready to assume the presence of duodenal stasis on insufficient evidence as an explanation for many ill-defined syndromes, including distress in the epigastrium and in the upper right quadrant of the abdomen. Thus, there has arisen a healthy skepticism and some hesitancy in accepting duodenal stasis as an unquestionable explanation for conditions which produce prolonged or recurring dyspepsia.

Duodenal stasis usually occurs in consequence of an organic disease in which there is actual blocking of the intestine. Such obstruction may develop from intrinsic or extrinsic causes. The more important intrinsic causes are usually assumed to be congenital narrowing, foreign bodies, pressure by diverticula, benign or malignant tumors or inflammatory diseases of the intestinal wall. Potential extrinsic causes include bands of adhesions, either congenital or acquired, enlargement or ptosis of the right kidney, anomalies or diseases of the pancreas, or extension of inflammation of the gallbladder. Pressure by an aneurysm or pressure by lymph nodes surrounding the intestine occasionally causes duodenal obstruction. At times, prolapse of the duodenum or pressure behind it pushes the intestine against certain blood vessels, such as the superior mesenteric artery and vein, and causes intermittent or chronic interference with normal emptying.

*Duodenal Tumors.*—Benign tumors of the duodenum are extremely rare. Balfour and Henderson reported a series of six such cases. In five of these cases the patients complained of some indigestion. They complained of dull pain in the epigastrium or right upper quadrant of the abdomen and usually complained of some nausea and flatulence. In three instances these symptoms exhibited some characteristics suggesting peptic ulcer in that the distress reached its maximum several hours following meals and was relieved by food or alkali. Gastro-intestinal hemorrhages occurred in three of these cases. The

six tumors included two myomas, two adenomas, one adenomatous polyp, and one hemangioma.

Although carcinomas which originate outside of the duodenum not infrequently invade the organ, primary carcinoma of the duodenum is extremely rare. Encroachment on the lumen of the duodenum by malignant lesions originating in the pancreas or extrahepatic bile ducts may cause mechanical disturbances which produce nausea or vomiting. Rarely, the duodenum is completely blocked by such lesions.

**Reflex Dyspepsias.**—In this group we shall consider epigastric hernia and disease of the gallbladder, pancreas, appendix, jejunum, ileum, and large bowel. About a third of all patients who have symptoms of a gastric disturbance will have a disease included in this group. The reason for this is apparent when it is realized that embryologically and anatomically these organs are very closely related to the stomach. The stomach physiologically may be likened to the thalamus of the brain, in which coarse sensations are appreciated but not localized.

It is interesting to note that both chronic and acute diseases of these structures may make themselves known first by dyspeptic symptoms. In the acute diseases, however, there is usually a rapid progression of symptoms with signs of localization which clarify the diagnosis. Mild disorders or the incipient stage of a severe pathologic process may exist for months without producing other symptoms than those of dyspepsia. Regardless of a good history, thorough examination, and extensive laboratory tests, it may not be possible to make an early diagnosis.

**Cholecystic Disease.**—Disease of the gallbladder accounts for about 20 per cent of all dyspepsia, a percentage greater than that attributable to all organic disease of the stomach and duodenum combined.

In acute or subacute cholecystitis, the situation of the symptoms is usually well localized in the upper right quadrant of the abdomen. There is likely to be tenderness and rigidity in the right infracostal region. Tenderness increases as the palpating finger approaches the lower margin of the ribs. The gallbladder may be palpable. The distress is fairly constant and is not relieved by the ingestion of food; on the contrary,

alimentation usually intensifies the symptoms for a brief period. There may be much flatulence and there may be a qualitative relationship between the ingestion of food and the symptoms; fats and fried foods are especially likely to intensify symptoms. The syndrome lacks the precision and clock-like regularity of that usually seen in cases of uncomplicated peptic ulcer.

An icteric or subicteric tint to the skin is frequently noted and a slight elevation of the icterus index or value for the serum bilirubin further tends to localize the disease in the gallbladder or bile ducts. The vomiting of blood, even in small amounts, or the detection of blood in the stools, is almost certain evidence that the lesion is not in the gallbladder. Roentgenologic investigation may be the deciding factor in making the diagnosis.

The detection of gallstones in the cholecystogram will confirm the diagnosis. Stones which have become impacted in a duct usually produce symptoms sufficiently definite to permit an accurate diagnosis to be made. Even then, there is always the possibility of associated lesions.

The differentiation of chronic disease of the gallbladder with stones and uncomplicated peptic ulcer is usually not difficult. Blackford and Dwyer called attention to two clinical types of cholecystitis with stones: (1) attacks of gallstone colic for years and then the gradual onset of chronic dyspepsia, and (2) chronic dyspepsia with milder attacks of acute indigestion, often followed by biliary colic. A carefully taken history almost invariably will disclose evidence which will suggest the presence of gallstones. The severity of gallstone colic is not easily forgotten and patients as a rule call attention to acute indigestion which they experienced perhaps many years previously.

The pain of gallstone colic usually comes on without much warning and it frequently stops just as quickly; however, it leaves residual tenderness in the upper right quadrant of the abdomen. Often, the site of the pain is epigastric, although it may start in the upper right quadrant of the abdomen. Usually, it is a deep-seated, through-and-through pain which often extends to the neck and right shoulder. It is severe, may be lancinating, and is often described as a pain "from which there seems to be no escaping except by hypodermics or vomiting."

The pain is intensified by associated upper abdominal flatulence which is severe. The breathing seems to be cut off because a deep breath intensifies the symptoms. Emesis occurs at times and the vomitus is usually greenish or yellowish. The attack may terminate quickly, with or without vomiting, but occasionally several hypodermic injections or even an anesthetic may be necessary to control the pain.

The cholecystogram has been of unquestionable value in helping to detect certain instances of cholecystic disease in which the symptoms were very indefinite and in which a pre-operative diagnosis otherwise would have been impossible. The so-called "reflex" of the gallbladder as a cause of indigestion is extremely indefinite. Clinical syndromes that have been assumed to be diagnostic of chronic disease of the gallbladder have been presented from time to time. These syndromes may include indefinite epigastric discomfort following meals, much flatulence in the upper part of the abdomen, nausea or vomiting after meals, and belching and bloating after the ingestion of certain types of food such as fats, fried foods, onions, or apples. In our experience such syndromes are unreliable as indications of cholecystic disease. We have noted that best results following surgical treatment of cholecystic disease in cases in which there was definite clinical evidence of the disease. This was also the observation of Judd, who carefully analyzed the surgical results in various types of cholecystic disease. He found encouraging results in cases in which there were inflammatory changes in the wall of the gallbladder even though these changes were slight; however, if the patient's symptoms are of the chronic dyspeptic type the likelihood that cholecystectomy will effect a cure is not so great.

*Appendicitis.*—Appendiceal dyspepsia may be classified as acute, subacute and chronic. In the acute and subacute forms the onset is usually characterized by epigastric discomfort or pain, fullness, belching, and nausea followed by vomiting which may or may not bring relief. The pain, which may originate anywhere in the abdomen, usually shifts to the middle or lower part of the abdomen and later becomes localized in the right lower quadrant. It must never be forgotten that the pain of acute appendicitis at times does not become localized over McBurney's point but may, as in the case of retrocecal appendi-

cititis, be found considerably above the usual site. Depending on the acuteness of the process there may be tenderness, muscular rigidity, fever and leukocytosis. The subacute form is difficult to diagnose because the symptoms are not acute and the signs not prominent. Accurate localization of the pain may not occur.

Some writers recognize a chronic form of appendicitis in which the symptoms are mainly dyspeptic in nature. There may be no history of previous acute attack of localized distress. It is our impression that periodic attacks of vague indigestion dependent on mild pathologic alterations in the appendix must be rare. Like the gallbladder, many normal appendices have been removed without curing the patient of his indigestion. An appendectomy or cholecystectomy may appear as a short cut to curing the patient, but the more logical course of action should be a laborious method of exclusion of other conditions or the watchful waiting for signs or symptoms which indicate localization of the process. Appendectomy for the cure of neurosis is usually a disappointing therapeutic procedure.

*Pancreatic Disease.*—Gastro-intestinal symptoms dependent on disease of the pancreas are common. In a review of eighty-eight cases of pancreatic neoplasms in which jaundice did not occur, Eusterman and Wilbur found that the most prominent symptoms were gastro-intestinal dysfunction, pain and loss of weight. The pain may simulate the pain of peptic ulcer, but it usually is more severe and persistent. The distress frequently originates in the umbilical region but it is situated often to the left of the umbilicus and is referred to the back; at times it is of such a severity as to require opiates. The character and situation of the pain, and the loss of weight, particularly if associated with putty-like, loose stools, should suggest pancreatic disease. In addition, if jaundice of even a mild degree becomes apparent or if a palpable mass is felt, suspicion should be directed to the pancreas. We recently saw a middle-aged man who had been ill for only seven weeks. Following an attack of diarrhea, which had lasted a few days, he had noticed a progressive anorexia, epigastric fullness, loss of weight, and steady, unremitting pain which was situated in the lower part of the thorax and extended bilaterally around the lower ribs. When he was admitted to the hospital there was a subicteric
